Mortality	67.5	30
Recovery	32.5	70.0
	Morbidity	
	Hospital days	Hospital days
Fatal Cases	18	22.8
Recovered Cases	80	53.8

The obvious values and limitations of penicillin therapy in the management of this condition are illustrated in a recent study of 90 cases of hemolytic staphylococcus septicemia at the Cincinnati General and neighboring hospitals between 1940 and 1946. A total of 40 cases of staphylococcus septicemia were treated with sulfonamides, surgery when indicated or bacteriophage between 1940 and 1943 and a similar series of 50 cases were treated with penicillin in addition to other medical and surgical medical measures between 1943 and 1946. Table V compares the two series in respect to mortality and morbidity indicating the profound effect penicillin has had upon this infection.

It is apparent that penicillin has approximately reversed the mortality and recovery rates. Whereas only 32.5 per cent recovered under sulfonamide, bacteriophage and other forms of therapy, 70 per cent recovered under penicillin therapy. A further analysis of the fatal cases reveals some of the limitations of penicillin therapy (Table VI).

The results in the cases developing vegetative endocarditis, particularly early in the series, were very poor and this condition accounted for almost half of the deaths. Of the remaining 8 fatal cases, 5 of the deaths occurred within 12 to 48 hours after their admission to the hospital and start of penicillin treatment. In these instances, the fulminating infection or moribund condition of the patient produced death before the maximum chemotherapeutic effect could become manifest. In the case of the infected burn, the *Staphylococcus aureus* was resistant to the action of penicillin.

The outcome in the individual case was dependent upon many factors (2-12) including the age of the patient, the susceptibility of the strain of staphylococcus to penicillin, the site

and nature of the primary infection, the duration of the bacteremia, the presence and location of secondary or metastatic abscesses, the accessibility of the primary or secondary infections to surgical drainage, and the presence of other associated and complicating diseases. Inadequate treatment predisposed to relapse. Experience has shown that treatment is not successful in young adults or children in whom the diagnosis of staphylococcal bacteremia is made early, penicillin therapy given early and intensively, and surgical drainage is possible when indicated.

Carbuncles. A carbuncle is essentially a spreading and necrotizing staphylococcal infection of the deeper layers of the skin and subcutaneous tissue which may result in extensive necrosis, sloughing, liquefaction of the subcutaneous tissue, septicemia, and death. The many forms of treatment which have been devised for carbuncles are an indication of our inability to control the locally or generally invasive characteristics of this infection. The great majority of surgeons have learned to employ crucial incisions or excision and because of the tendency of carbuncles to extend locally or invade the general circulation, the treatment of choice at many clinics, including the Cincinnati General Hospital, has been radical excision. Sulfonamide therapy in general has been disappointing due principally to the natural resistance of the hemolytic *Staphylococcus aureus*.

The marked effect of penicillin on the management of carbuncles is shown in a group of 40 cases with carbuncle which we have treated with penicillin between February, 1944, and October, 1946. 8 of which received both penicillin and sulfadiazine. The dosage employed was 12,000 to 20,000 units every 3 hours given intramuscularly in every instance but one in which it was given intravenously. The average

Fig 3 J B aged 8 years acute hematogenous osteomyelitis with bacteremia and metastatic pericarditis. Chart shows failure of response to penicillin therapy until metastatic infectious complication in the form of a pericarditis is recognized and treated as indicated.

total dose was 927 000 units and the average duration was 7 days

The results of treatment indicate that penicillin is obviously the chemotherapeutic agent of choice in this type of infection. When given early in sufficient amounts and over a long enough period of time it brought the general and local invasive manifestations under control within a period of 48 to 72 hours and so modified the subsequent course that both mortality and morbidity were reduced. In our experience penicillin therapy was followed by complete and spontaneous resolution in 26.5 per cent of the cases (Figs. 4 and 5) by partial resolution with centralized necrosis in 22.4 per cent of the cases with partial resolution and abscess formation in 49.0 per cent of the cases, and by failure in 2 per cent of the cases. Thus it was not necessary to subject these patients to emergency total excision of the lesion in

order to control this infection. Since the invasive qualities have been controlled so effectively with penicillin more limited surgical procedures are recommended when indicated consisting of incision and drainage of abscesses occurring during therapy and cruciate incision for the removal of necrotic tissue.

Acute hematogenous osteomyelitis. In the past the results of treatment in this condition have been unsatisfactory for several reasons. Difficulties in diagnosis often resulted in delay and spread of the process with extensive destruction of the bone. When early diagnosis

Fig. 4. F. H. aged 43 years, admitted to Cincinnati General Hospital, August 9, 1944, with a large carbuncle of the neck of 5 days duration. Temperature and pulse remained normal after the third day. a, left, Appearance of carbuncle on August 3, 1944. b, start of treatment with penicillin. b, August 12, 1944, disappearance of the carbuncle and almost complete healing have occurred in 9 days.

was made, the principal method of arrest and control of the necrotizing process was emergency decompression of the involved area by surgical drainage followed by prolonged periods of immobilization. More recently chemotherapy with the sulfonamides used as a supplement to surgical intervention aided in the control of the infection but left much to be desired. Penicillin on the other hand has had a profound effect upon acute hematogenous osteomyelitis and has greatly modified both its management (8, 14, 19) and roentgenographic interpretation (9). In the group of 64 cases of acute hematogenous osteomyelitis treated with penicillin the mortality rate was remarkably low being 1.5 per cent. In general the other results of penicillin therapy varied primarily with the time of diagnosis and start of treatment falling into 4 groups.

The first group included those cases in which the correct diagnosis was made within the first 3 or 4 days, and adequate treatment was started immediately. The results were truly excellent surgical intervention usually being unnecessary and abscess formation infrequent. After a period of 36 to 72 hours, the fever, rapid pulse, bacteremia and other general

signs of the severe infection began to disappear. At the end of a week the temperature was usually normal and the patient looked and felt quite well. The local signs of infection, such as tenderness, edema, and redness, also began to recede after a similar latent period. During the next 1 to 6 months a series of roentgenographic changes occurred in the involved bone which were minimal consisting of localized periosteal reaction or small areas of patchy decalcification of the underlying cortex, or both. These findings occasionally were hard to see and could be easily overlooked.

In the second group in which the diagnosis and treatment with penicillin were moderately delayed for 4 to 7 days, the general and local infections were brought under control by penicillin less promptly after a period of 2, 3, or more days during which little or no clinical response was evident. Localized soft tissue abscesses occasionally developed and when small, they were successfully treated by aspiration and local injections of a solution of penicillin. When large surgical drainage by incision was done to minimize further tissue destruction by the accumulated necrotizing bacterial toxins. If surgical drainage was insti-

Fig 5 V L., aged 33 years. a left, Carbuncle of face with diffuse cellulitis, thrombophlebitis of facial, external, and anterior jugular veins, staphylococcal bacteremia, and bilateral pneumonia. Temperature, 106 degrees F at start of penicillin therapy b Effect of 10 days therapy with penicillin.

tuted the fall of temperature was usually prompt and not delayed for 36 or more hours as in the case treated without surgical intervention

After a week or more had elapsed periosteal reaction and localized patchy demineralization of the underlying metaphysis became evident in the roentgenograms and increased in extent and degree becoming most marked 1 to 5 months after the onset of the infection. Recalcification of the demineralized areas followed with re-establishment of a more normal appearance of the bone. Sequestration rarely occurred in this group.

The third group included cases in which the diagnosis and treatment were delayed for 7 to 10 or more days and those in which the infection was unusually severe. The local destruction of bone became very great and soft tissue abscess formation and sequestration occurred in most, but not all of the cases. The local infection was arrested with more difficulty in this type of case and longer periods of treatment with penicillin were usually required. Small abscesses were treated by aspiration and large ones by incision and drainage. Prolonged immobilization by cast in these cases seemed to be definitely indicated.

The bony changes as revealed by serial roentgenograms at the start of penicillin treatment showed extensive bone destruction which increased on subsequent examinations. Se-

questration occurred in most cases and in many instances the smaller sequestra were gradually absorbed spontaneously.

The fourth group included certain fulminating infections in which the patient would not live 48 or more hours to permit the maximum effect of penicillin. Surgical intervention after adequate preoperative preparation was necessary as an emergency measure in addition to intensive penicillin therapy.

In general the effects of penicillin included control of the generalized infection with sterilization of the blood stream, reduction of the mortality rate, and decrease in the incidence of metastatic or secondary infectious complications. If metastatic complications such as staphylococcal pneumonia, pleuritis, pericarditis, thrombophlebitis, etc., already existed penicillin was a powerful chemotherapeutic agent aiding in their control as an adjunct to surgical or conservative treatment as indicated. Thus the morbidity was also decreased.

There seems to be little doubt that adequate penicillin therapy can eliminate the necessity of emergency surgical intervention in most cases of early acute hematogenous osteomyelitis (8, 14, 19). It must be emphasized that early diagnosis can be made only on clinical grounds and that little or no help is to be expected from the roentgenograms for 10 or more days. If there is any doubt as to the presence of an acute osteomyelitis it is better

Fig. 6 M. K. a, left, Severe acute hemolytic streptococcal cellulitis of face, neck, and scalp, with gangrene which was resistant to sulfonamide therapy. Temperature was 105 degrees F at start of penicillin therapy. b, Appearance of lesion after control of infection, separation of sloughs, and preparation of area for skin graft.

to start penicillin therapy rather than wait until the diagnosis is proved.

Of particular interest were the resultant roentgenographic changes which occurred in the involved bone treated with or without surgery. During the period of penicillin therapy evidence of bone damage was absent or confined to minimal changes such as slight periosteal reaction or small areas of demineralization in the underlying cortex. After the cessation of chemotherapy the periosteal reaction and mottled appearance of the underlying bone progressively increased, reaching a maximum 1 to 5 months after the onset of the infection. In this way the bone always looked worse a month or more after penicillin therapy than during it. This picture has been interpreted as being the result of spontaneous absorption of bone destroyed early in the infection and not as the result of continued destruction of bone by an extending chronic osteomyelitic process. Following this recalcification of the involved areas occurred often very rapidly. Meanwhile normal growth of the metaphyses, calcification of the adjacent

epiphyses, and return of function occurs. These facts suggested that adequate penicillin therapy may sterilize the infected bone converting an area of septic necrosis to one of aseptic necrosis. One of the most important aspects of this problem remains unanswered as yet: the question as to whether or not the infection has been completely cured.

Chronic osteomyelitis. In chronic osteomyelitis the results were usually disappointing unless penicillin therapy was used in conjunction with radical surgery. Spontaneous resolution of an acute exacerbation was noted in only 9 instances. In the remainder surgery was necessary along with penicillin to clean up the local infective process.

Acute secondary or postoperative parotitis. The control of acute secondary parotitis by chemotherapy is desirable since its arrest by conservative measures is uncertain and its control by surgical incision and drainage has certain disadvantages. Incision may result in unsightly scars, occasional injury to the facial nerve, salivary fistulas, or troublesome secondary infection (5). In addition a general anes-

TABLE VIII.—AEROBIC STREPTOCOCCAL INFECTIONS—RESULTS OF PENICILLIN THERAPY

Septic abortion	1	0	2	2	1

thetic and operation unquestionably throw an added burden upon the patient greatly weakened by some other primary disease which predisposed to the development of the acute parotitis. The simplicity of administration and the directness of action of effective chemotherapy largely obviate these disadvantages. Of 6 patients treated with penicillin 4 underwent complete and spontaneous resolution. A fifth responded satisfactorily to penicillin after failing to respond to Lugol's solution. The sixth underwent partial resolution with the formation of an abscess which was incised.

The general response of this infection to penicillin therapy followed the general pattern seen in other surgical infections treated by chemotherapy. An interval of 24 to 48 hours following the start of treatment preceded the development of obvious signs of clinical improvement. Thereafter the improvement was progressive and usually rapid.

Aerobic hemolytic streptococcal infections. While most of these infections respond promptly to sulfonamide therapy penicillin is also very effective and particularly valuable in those cases resistant to the sulfonamides (Fig. 6). The results of therapy in cases of hemolytic streptococcal infections treated at this Hospital most of which were sulfonamide resistant, are summarized in Table VIII.

TABLE IX.—ANAEROBIC STREPTOCOCCAL INFECTIONS—RESULTS OF PENICILLIN THERAPY

		Excellent	Good	Questionable	Failure
Bacteremia	6		1	1	2
Septic abortion	0	2	6		1
Chronic burrowing ulcer	5			3	
Chronic progressive cutaneous gangrene	2				1

In the treatment of anaerobic streptococcal infections, penicillin was far superior to the sulfonamides (3). *In vitro* studies showed its bacteriostatic action under anaerobic conditions for the anaerobic streptococci to be far greater than that of the sulfonamides. We have had an opportunity to use penicillin therapy on 22 cases of anaerobic streptococcal infections and the results are shown in Table IX.

Pneumococcal infections. The average pneumococcal infections seen in surgical practice respond very well to sulfonamide therapy in much the same manner as do the hemolytic streptococcal infections. Penicillin therapy was therefore reserved for those cases which were sulfonamide resistant and the results obtained in 70 cases are shown in Table X.

Tetanus. A clinical study (6) of 22 cases of established generalized tetanus seen in and about Cincinnati has failed to show evidence of any beneficial effect of penicillin on the course of this disease. There was no obvious

fall in the temperature or pulse rate as has been repeatedly seen in other infections susceptible to its action no decrease in mortality or morbidity nor any definitive decrease in the severity, duration or frequency of the convulsive seizures which could be attributed to the action of penicillin. Exceptions were found in cases complicated by pneumonia or other secondary infections susceptible to penicillin in which the improvement that occurred was due to the effect of penicillin on the complicating infection and not on tetanus. The evidence indicates that the successful management of tetanus depends not on chemotherapy but on early diagnosis, adequate serotherapy for neutralization of free toxin, control of the convulsions and the administration of general supportive measures.

Human bite infections When once established this type of infection has been controlled with considerable difficulty in the past. Its necrotizing burrowing characteristics have resulted in prolonged morbidity, extensive septic necrosis of the tissues including bone, toxemia, impaired function, and even amputation. The results with penicillin therapy in 9 cases have been very promising and they indicate that penicillin is a valuable therapeutic agent for this condition, being superior to the sulfonamides. In 5 of the cases the response to paren-

teral penicillin therapy, rest, immobilization and elevation was excellent, the infection subsiding quickly and spontaneously with little or no evidence of residual infection or damage. The response was good in 3 other cases when penicillin was used in conjunction with incision and drainage, and questionable in the remaining infection.

Ratbite fever Ratbite fever is essentially an invasive wound infection of two clinical types: (1) *sodoku* caused by the *Spirillum minus* and (2) the *septicemia* form produced by *Streptobacillus moniliformis* (10). The endemic Japanese form, *sodoku*, has responded to arsenotherapy but no satisfactory form of treatment was known for the streptobacillary type. The first 4 cases of ratbite fever caused by the *Streptobacillus moniliformis* which were treated with penicillin were studied at the Cincinnati General Hospital. The results of penicillin therapy in these 4 cases were excellent: in 3 with sterilization of the blood stream, early fall in temperature and pulse, disappearance of rash and arthritis, and shortening of the course of the disease. In addition studies *in vitro* indicated that penicillin has a powerful bacteriostatic effect on the *Streptobacillus moniliformis*.

Gas gangrene. Penicillin is by far the chemotherapeutic agent of choice in the control of

established gas gangrene. Clinical investigations indicate that parenteral penicillin used in conjunction with surgery gives encouraging results, but only when it is given in relatively large doses of 200 000 to 400 000 units and 800 000 units per day (11, 16, 18). In a study of experimental gas gangrene (7) the therapeutic value of penicillin has been determined quantitatively.

Average doses of penicillin had no measurable effect, but large doses corresponding to approximately 1 000 000 units given every 3 hours had a very definite effect, reducing the mortality, prolonging the life of the guinea pigs and localizing the lesions. Without surgery, however, discontinuation of penicillin was followed by prompt spread of the lesion and ultimate death. These experiments indicate clearly that penicillin in large doses is a valuable adjunct to adequate surgery in the treatment of established gas gangrene, since it limits the spread of the lesion, prolongs the period during which surgical decompression and excision of involved muscles can be done successfully and reduces mortality. This corresponds to the clinical impression of Jeffrey and Thomson obtained in 33 cases of gas gangrene that penicillin can arrest the progressive myositis, but that radical surgery is still the main factor in treating the disease. In our clinical experience of 12 cases of gas gangrene, the use of penicillin in conjunction with surgical decompression or amputation seemed to be of definite value in overcoming the invasive manifestations of the infection. If the diagnosis was made at an early stage while the gangrene was more or less localized and incipient, radical decompression of the involved fascial compartments by free longitudinal incisions and excision of the infected muscle usually resulted in the arrest of the process and the saving of the extremity. If the diagnosis was made late when the process was extensive and had caused irreversible gangrenous changes in the extremity, implying loss of function of the limb, open amputation of the girdle type or some modification became necessary (Fig. 7). At the present time it is inconceivable that any type of serotherapy or chemotherapy can replace good surgery in the treatment of gas gangrene.

Actinomycosis. Penicillin has been much more effective than the sulfonamides in the treatment of actinomycosis, but in our experience it is used most effectively in conjunction with sulfadiazine or sulfamerazine. Penicillin given in full doses over a prolonged period of at least 4 to 8 weeks in association with sulfadiazine which is continued under control for an additional 4 to 6 months has given us the best results. Very satisfactory results were obtained in the cervicofacial type and other cases of both abdominal and thoracic actinomycosis have undergone arrest and rather spectacular regression under this management with progressive decrease in size and finally disappearance of the tumor masses and pain. Whether or not complete cures have been obtained in these cases remains to be seen.

SUMMARY

It is evident that the sulfonamides and penicillin are very effective and useful agents in the treatment of many infections commonly encountered in the practice of surgery. Penicillin is far superior to the sulfonamides in the treatment of infections caused by the staphylococcus and it has been particularly useful in the cases of infection caused by sulfonamide resistant gonococci, hemolytic streptococci and pneumococci. It is also the chemotherapeutic agent of choice in gas gangrene, rat bite fever, actinomycosis, anaerobic streptococcal infections and human bite infections. The use of increasingly large doses of penicillin permitted by its very low toxicity is gradually extending the field of effective chemotherapy in other infections produced by less susceptible bacteria. Penicillin has been strikingly effective in diffuse or generalized staphylococcal infections which have been diagnosed and treated early with penicillin, with the exception of those caused by a resistant strain or those complicated by acute vegetative endocarditis. The early treatment of diffuse infections caused by the staphylococcus or streptococcus often was followed by such prompt and complete arrest of the destructive bacterial process that suppuration did not develop and surgical intervention either became unnecessary or limited to more localized measures. In

the management of suppurating surgical infections caused by susceptible bacteria, penicillin therapy has had a striking beneficial effect on mortality and morbidity but the fundamental surgical principles of early accurate diagnosis early treatment rest, adequate external drainage correction of altered physiology and vigilant supportive treatment remain as important as ever

CANCELLOUS BONE GRAFTS TO THE JAW

T G BLOCKER, Jr MD F.A.C.S Galveston Texas

THE problem of bone grafting in the lower jaw merits serious consideration even though it is met with infrequently in civilian practice. Distortion of appearance which results from mandibular loss in the course of surgery of malignancy and following severe infection or trauma is secondary in importance to disturbance of

speech and to the impairment of mastication and deglutition which affects profoundly the individual's entire nutritional status. In war surgery the necessity of bone grafting to the lower face arises rather commonly because of the high incidence of massive maxillofacial injuries from bullets and shell fragments.

Mandibular bone grafts were first employed 30 years ago during World War I by the German, French and English American groups of workers with perhaps a thousand cases re-

Presented in the symposium on Plastic Surgery of the Head and Neck, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

Fig. 1. O. R. L., Pfc., age 21 years, received a shell fragment wound June 29, 1944, with loss of considerable soft tissue of the chin and bony loss of the symphysis and anterior half of the right body of the mandible. It was necessary to readjust soft tissues for better coverage before insertion of a bone graft, and a labioalveolar sulcus was created later by a stent graft in order that a functioning

denture could be used. a, Appearance on admission. b, Roentgenogram showing bone loss. c, Interlocking cap metal splint for immobilization. d, Roentgenogram showing cancellous bone graft bridging the defect. e, Appearance following bone graft.

ported in all. A variety of sources were employed in the remedy of small losses of bone and in ununited fractures. These include

1. Sliding or pedicle grafts from the mandible for losses not greater than 3 centimeters in the symphysis or body

2. Cortical grafts from the tibia

3. Osteoperiosteal grafts—thin shavings of bone and periosteum about 2 millimeters in thickness—for small bony defects not associated with disturbance of contour

4. Rib grafts

5. Clavicle grafts employed in pedicles from the neck for restoration of the symphysis and overlying soft structures of the chin

6. Grafts from the ilium, particularly for large losses of bone and distortion of normal contour

During recent years the use of iliac grafts has been the method of choice, although some workers, notably Barrett Brown, employ the rib whenever practicable.

(Legend on opposite page)

The literature on theories as to the mechanism of bone regeneration is voluminous and has influenced considerably the operative technique. For a long time it was felt that periosteum was indispensable but experimental and clinical evidence has demonstrated that neither periosteum nor cortical bone is necessary for successful grafting. The superior qualities of cancellous or spongy bone provide for rapid vascularization and earlier stabilization and union for this reason small chips of part-cortical part-cancellous bone are becoming increasingly popular in orthopedic and maxillofacial surgery when it is felt that immobilization can be maintained without the use of cortical bone as a splint for fragments. The employment of large blocks of pure cancellous bone from the ilium is the most recent innovation in bone grafting. And while other workers may be able to demonstrate equally good results with other methods of reconstruction of mandibular defects we have found cancellous block grafts an extremely satisfactory medium of repair. The ilium is readily accessible and furnishes a large amount of available spongy bone. Following removal

of all cortex the graft is easily cut and shaped to fit the requirements of the individual case. The use of chips alone is rather haphazard and it is difficult to maintain good contour. For extensive defects such as angle-to-angle loss of bone we have employed at times a tantalum tray to give proper shape to the jaw. In these cases more than one block graft is used, and cancellous chips are packed around the open spaces.

With present-day dental appliances there need be no dependence on the mandibular graft for any part of fixation. Cancellous bone very quickly develops strength and evidence of firm bony union within 8 to 14 weeks time after operation when dentures may usually be fitted. We have been able to observe grafts directly 5 to 6 months after surgery when exposure is made to add a cartilage implant for improvement of chin contour. They show smooth white bone with a well-developed pseudoperiosteum and on stripping of this membrane numerous nutrient vessels are seen entering the bone.

The most important requirements for success in bone transplantation are adequate sup-

Fig. 3. V. A. Mc., age 30 years, received a machine gun bullet wound of the face October 17, 1944, with violation of the soft tissues about the lower lip and floor of the mouth and loss of the symphysis and anterior half of each body of the mandible. a, Appearance on admission. b, Appearance following rearrangement of local tissues to stop the salivary leak and raising of pedicle soft tissue from the chest to be used for reconstruction of the floor of the mouth prior to bone grafting. c, Interlocking cast metal splints for stabilization of the fragments. d, Appearance following bone graft.

ple cover free of scar tissue and induration, absence of infection and avoidance of contamination at the time of operation and proper preoperative and postoperative immobilization of fragments. The necessity of having resilient soft tissue covering has not been adequately stressed and here time is an inescapable factor in the elimination of wound reaction. For avulsion deformities pedicle flaps from the thorax and abdomen must be employed. Less severe defects may be taken care of by rotational flaps and other methods of rearrangement of local tissues. Even small adherent scars should be removed several weeks before bone grafting with complete excision and wide undermining to give relaxation in closure. Operation should never be performed through a wide cicatrix or through an indurated area. Removal of loose sequestra and fragments of teeth hastens the subsidence of localized drainage and infection. We are not yet convinced that early operation is advisable

even with the use of penicillin and it has been our custom to delay bone grafting for a minimum period of 2 months following last drainage from the area. The great majority of our cases have waited over 6 months after subsidence of active evidence of infection.

Bone grafting to the jaw requires close cooperation of both surgeon and dentist. The dental surgeon assumes charge of all mechanical devices for immobilization of fragments before and at the time of operation and looks after the patient's oral and dental hygiene. Proper emphasis must be placed upon improvement of the general physical condition as well with correction of anemia, weight loss, and protein imbalance.

The chief problem in individual bone graft procedures of the mandible is the method of fixation and immobilization to be employed. Various factors must be taken into consideration: size and character of the defect, position of teeth in the upper and lower jaw and state

Fig. 4. R. M. B. Corporal aged 35 years, received a shell fragment wound June 10, 1944, with avulsion of soft tissues of the chin and floor of the mouth and loss of the right body and symphysis of the mandible. a, Appearance on admission showing granulations and draining sinuses.

b, Exposure of mandibular defect at operation 1 year after admission. Soft tissue loss has been replaced with a pedicle flap from the chest. c, Tantalum tray containing cancellous block graft. d, Appearance following operation. e, Profile view.

of occlusion of the fragments. Because of the danger of opening into the oral cavity at the time of operation the position of fragments cannot be altered at that time except in angle defects or where the fragments are edentulous.

If both fragments are edentulous some modification of the Gunning splint is used during the waiting period and also following bone grafting. At operation we usually employ some type of internal fixation such as a piece of perforated tantalum shaped over an impression of a normal cadaver mandible.

Where one fragment is edentulous and the other contains teeth the latter is kept in occlusion by a flange splint. The edentulous portion at operation is liberated on all surfaces, placed as nearly as possible into normal

position and maintained there by a wire through the angle tip or ramus which protrudes through the skin and attaches to a bar coming around the face from the intraoral splint.

Where both fragments contain teeth a cap metal splint with rigid crossbar is very satisfactory preoperatively. At the time of insertion of the graft two interlocking cap metal splints are used to hold the jaws absolutely immobilized. At the time of operation we have employed either endotracheal anesthesia or a combination of (1) high bilateral intraoral mandibular block with 2 per cent novocain, (2) local novocain infiltration and (3) spinal anesthesia for removal of bone from the ilium. We prefer the second method because of the advantage of novocain adrenalin solution in

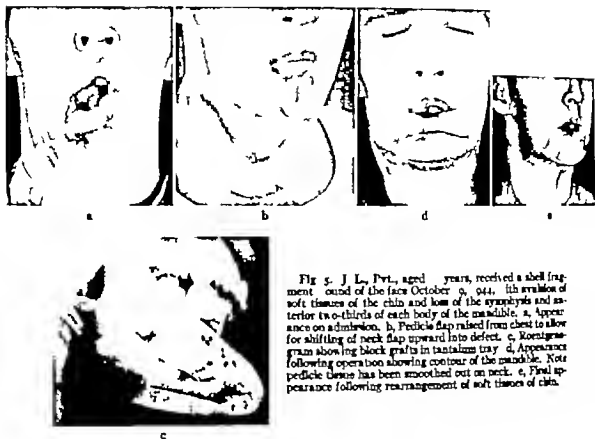

Fig. 5. J. L., Pvt., aged _____ years, received a shell fragment wound of the face October 9, 1944, with avulsion of soft tissues of the chin and loss of the symphysis and anterior two-thirds of each body of the mandible. a, Appearance on admission. b, Pedicle flap raised from chest to allow for shifting of neck flap upward into defect. c, Roentgenogram showing block grafts in tantalum tray. d, Appearance following operation showing contour of the mandible. Note pedicle tissue has been smoothed out on neck. e, Final appearance following rearrangement of soft tissues of chin.

minimizing bleeding in the operative field. In addition the patient is less likely to develop postoperative respiratory distress and nausea when a general anesthesia can be avoided.

TECHNIQUE

The operative technique is as follows:

Incision is made parallel to the lower border of the mandible with care taken to prevent injury to the mandibular branch of the facial nerve. This nerve can be avoided by dissection downward external to the platysma for about 2 centimeters below the inferior border before approach is made to the bone fragments. About 2 centimeters of bone is exposed on each side where fragments contain teeth. For ramus, angle, or posterior edentulous fragments exposure can be made by stripping the periosteum for long distances without danger of entering the oral cavity. Edentulous fragments are detached thoroughly and replaced in normal position.

Eburnated ends of fragments are cut off by sharp rongeurs, and the outer cortex of the

mandible in the recipient areas is removed with a dental burr until an area of bleeding bone sufficient for good contact is obtained.

Meanwhile the iliac crest has been exposed subperiosteally by another operative team. A large section of ilium is cut out with a sharp osteotome and placed on a wooden block for removal of all cortical bone, which is then discarded. The donor area is closed in layers with a deep removable No. 32 wire suture and No. 36 interrupted sutures are used for the skin. Pressure dressing is applied.

The graft is shaped with sharp-cutting rongeurs, and all cancellous chips are saved to be packed later into open spaces in the graft bed. The transplant is placed in position as both an inlay and onlay graft and is immobilized by a single strand of No. 32 stainless steel wire at each end. At least 2 centimeters should be in contact with the bleeding bone on each fragment. Although there may be marked protuberance externally at first, rapid absorption takes place and the contour of the mandible is quickly established after function begins.

Fig. 6. F W P. Pvt., aged 20 years, received a shell fragment wound July 7, 1944, with avulsion of the lower lip, chin, and floor of the mouth, and loss of the symphysis and anterior one-third of each body of the mandible. a, Appearance 3 months after injury. b, Pedicle flap in position. c, Roentgenogram showing bone loss. d, Interlocking cap metal splint used for immobilization of fragments before bone grafting. e, Roentgenogram showing bone graft in position. f, Appearance following firm bony union. g, Appearance following excision of outer covering of flap and replacement with skin from the face. Further "touching-up" procedures are yet to be carried out.

Complete hemostasis is obtained by ligation of all bleeding points with No. 40 wire. Closure is made in layers, and firm pressure dressing is applied. It cannot be too strongly em-

phasized that there must be no tension on the wound edges and it may be necessary for proper relaxation of the tissues to undermine the skin for considerable distance.

Fig 7. J. P. P. Pvt., aged 19 years, received shell fragment wound of the face June 24, 1944, with fracture of the left mandible and maxilla. Following removal of an unsuccessful cartilage graft because of drainage, a large cancellous bone graft was placed over the remaining portion of the maxilla, with good contour resulting. a, Appearance on admission. b, Final contour.

(Reproduced through courtesy of the J. B. Lippincott Company from article by Blocker.)

Fig 8. C. C. Pic, aged 19 years, received shell fragment wound of the face July 5, 1944, with violation of soft tissue and loss of the major portion of the left maxilla. The soft tissue loss was replaced by pedicle skin prior to restoration of contour by cancellous block graft. Appearance on admission. b, Appearance following operation. It is planned to remove the outer covering of the pedicle flap as completely as possible later and replace it with a rotational flap from the neck.

(Reproduced through courtesy of the J. B. Lippincott Company from article by Blocker.)

In over half of our cases closure was made with fine silk, but as we felt that in two instances drainage occurred as a result of buried silk sutures, we began to use a single removable stainless No. 36 wire for the deeper layers and continuous running stitch of No. 38 wire for the skin.

AFTER-CARE

Postoperatively patients are kept in a semi-sitting position and watched closely for evidence of respiratory difficulty. In one instance we found it necessary to open an intraoral splint for 24 hours to relieve obstruction. Liquids are given by syringe or tube and gradually the patients learn to put semisolid foods around the splints with the fingers. Protein and vitamin intake is given careful attention.

Routinely we have given for 5 days postoperatively 20,000 units of penicillin in $\frac{1}{4}$ per cent novocain solution every 3 hours. Pressure dressings to both donor area and face are maintained for 10 days, and frequent mouth wash is used for oral hygiene. Patients are usually ambulatory by the end of 2 weeks. After 7 or 8 weeks the cap metal splints are released, and the state of clinical union is inspected. If the fragments are not absolutely rigid, splints are left in place for another 2 to 4 weeks before removal. Dentures are fitted within 8 to 14 weeks if normal buccal and labioalveolar sulci are present. Otherwise these must be reconstructed by stent grafts 4 to 6 months later.

During the past $2\frac{1}{2}$ years we have seen in an army plastic surgery center 68 patients who have required bone grafting because of mandibular loss greater than 2 centimeters. Eight of these showed massive avulsion wounds which required replacement of soft structures by pedicle flaps prior to bone grafting. Two of the 68 patients are still waiting final operation pending subsidence of tissue reaction.

In the remaining 66 cases blocks of pure cancellous bone from the ilium have been employed for defects varying from 3 to 15 centimeters in length. Drainage has occurred in 10 instances twice from buried silk, three

times from inadequate coverage and in 5 cases from accidental opening into the oral cavity. Half of these cases have had successful union in spite of drainage. Four have had partial loss of graft. 2 of these have since been regrafted without complication. In the fifth case it was necessary to remove the transplant because of infection. Failure has been attributed in 3 instances to insufficient cover plus difficulty in fixation for one reason or another in 2 there had been infection following entrance into the mouth.

No disability has been noted in any patient from the removal of bone from the ilium. Drainage has occurred in 2 instances once from buried silk and once from a small piece of rubber tissue inadvertently left in the wound.

In addition to 68 bone grafting procedures to the mandible in 66 patients cancellous iliac grafts have been employed for restoration of contour in 18 deformities of the maxilla. 5 of the nose and 2 of the supraorbital margin. Drainage occurred in one instance but successful final union was obtained in every one of these cases.

SUMMARY

In summary we believe that iliac block grafts of pure cancellous bone form the most satisfactory material for relief of large and small bony defects in the mandible. The large percentage of cases without failure cannot be attributed to the choice of graft alone however. We must not overlook the value of chemotherapy in the treatment and prevention of infection nor disregard the importance of suitable mechanical fixation of fragments. Above all we must not forget that the background of all transplantation procedures is the proper preparation of the tissues themselves. In no other branch of surgery is the old adage so true, that haste makes waste.

MODERN METHODS IN THE TREATMENT OF FRACTURES

EDWIN W RYERSON M.D. F.A.C.S., Chicago, Illinois

IN the early days of the human race, nearly all fractures were caused by falling from a sufficient height and were usually simple fractures of the long bones. As the centuries rolled by and warfare became developed to a higher grade than wooden clubs and stone axes, compound fractures became more common and were less easily repaired. With the advent of gun powder and the hazards of more rapid transportation fractures occurred with much greater frequency and began to attract the serious consideration of the physicians and surgeons of those times.

Seventy years ago a compound fracture of an arm or leg almost invariably required immediate amputation to save the patient a life, but the development of antiseptic and aseptic methods of treatment began to offer more hope of saving these damaged limbs. Forty years ago the rapidly increasing numbers of automobiles introduced the tremendous risks of high speed travel on the highways and the byways of the world. Thirty years ago the first World War produced the enormous dangers of high explosives and fast airplanes and these dangers were multiplied many times over in the war which ended only last year. Or has it really ended?

What has been learned in the last few decades about the treatment of fractures? Since 1900 forty six years ago I have been interested in orthopedic surgery and in fractures. I have seen the rise and sometimes the fall of many different methods and ideas in the treatment of broken bones.

The one dominant purpose of treatment is to produce a satisfactory union of the fracture, with re-establishment of the normal function in the shortest possible time.

In the Fracture Oration of 1935 Paul Magnuson presented briefly and graphically

Dr. Ryerson is Consulting Orthopedic Surgeon, St. Luke's Hospital, Chicago.
Fracture Oration, presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1935.

the salient points of fracture treatment from the days of the Egyptians 4500 years ago, the Hippocratic era 2400 years ago, and the works of Galen up to the year 900 Anno Domini. Then came the long centuries of the Dark Ages when no progress was recorded until the Renaissance. In the 14th century interest in fractures was revived and from that time the value of many of the almost forgotten old principles began to be recognized. Methods of traction and countertraction, the basic foundation of the treatment of fractures of the long bones, became simplified and improved. Buck's extension Thomas's splint (which was originally designed for knee disorders) and the Hodgson suspension splint gradually assumed their well deserved importance, together with the improved types of adhesive plaster. Then in 1895 came Roentgen's discovery of the x ray which visualized both the good and the bad results of treatment, and made possible some much needed improvements in the handling of fractures.

Now it became easy to determine accurately whether or not the alignment of a fractured femur was satisfactory or whether the traction was pulling the bones too far apart.

Next came the development of skeletal traction by Steinmann's pin and Kirschner's wire, in cases in which adhesive plaster could not be used. These devices were not free from the danger of infection and had to be carefully watched.

In 1910 Arbuthnot Lane popularized his method of applying a steel plate, by open operation screwing it across the fracture-line by four or six or eight screws. This simple and easy way of reducing and securing fractures of the long bones swept the country like a tornado. It seemed so rational and so satisfactory that hundreds of surgeons purchased the plates and the few special instruments, and without following the meticulous technique perfected by the originator proceeded to plate many simple fractures of the long bones. I do not know how many times I have been asked

to see a boy or a girl with a fractured femur who was about to have a Lane plate applied by an enthusiastic surgeon. In most of these cases when it was explained that the overriding and the malposition could be corrected by a few days of traction and suspension in a weeks union would be strong enough for a caliper splint or a plaster-of Paris spica the doctor and the patient were willing to avoid the operation.

There are two basic reasons entirely apart from the danger of infection why a plate of the Lane type or the Sherman type or any similar type is not the ideal method of treatment. First, it does not immobilize the fracture completely, because a certain small amount of motion will always be present in rotation and in lateral bending toward the plate. Both of these motions could be avoided by applying a similar plate to the opposite side of the bone but few surgeons have had the hardihood to attack the bone on both sides. In oblique fractures a transfixion screw applied at right angles to the line of fracture will prevent most of the mobility but does not work so well in transverse fractures. Secondly when a Lane plate is applied the ends of the fragments undergo a small amount of absorption so that a definite space is left between the ends. It is true that in many cases enough new bone is formed to obliterate this empty space, and the fracture unites but it does not unite as rapidly as it would if the bone ends were in firm contact. Moreover the external callus formation develops upon the opposite side of the fracture and does not cover the plate, except in children so that the ultimate ossification of the fibrous tissue between the ends of the bones is greatly delayed. This external callus may become very large when the immobilization of the fracture is inadequate. Even a long plaster-of Paris cast, from the chest to the toes does not furnish complete immobilization in most cases of fracture of the shaft of the femur.

I do not deny that in many hospitals and clinics the plating of simple fractures of the long bones has shown excellent results but such operations should be performed only when a satisfactory result cannot be obtained

by conservative mechanical means and when the surgical standards of the operator and of the hospital are of the very highest grade.

Because of the many disappointments following the widespread use of the early types of the Lane plates whether from mechanical defects technical errors or infections, other investigators have been busily devising different methods. The old and reliable principles of manual reposition traction and counter traction and fixation by plaster of Paris and splints have become less understood and less popular. This I think is largely due to the fact that the conservative mechanical treatment of long bone fractures requires the careful time consuming attention of the surgeon himself. He cannot safely delegate this attention to anyone else. A leg or an arm in a traction apparatus must be seen every day by the man who is responsible for the ultimate result. Residents and internes do not always notice that the adhesive plaster is cutting into the skin or is losing its pull at important points. Because this constant attention is necessary and because a day has only so many hours, it is perfectly natural that busy surgeons should welcome any methods which would reduce the time element required for proper results. If such methods are safe, sane and satisfactory we should use them but we must always remember that the union of a fracture takes so many weeks or so many months and that we cannot make broken bones grow together any faster in 1946 than the Egyptians could four thousand years ago.

What are some of these newer methods and to what extent can they be recommended for general use?

Many years ago various types of nails and screws were employed in attempts to fasten together the broken bones. Considerable success resulted in many cases but the ever present danger of infection made such treatment always a definite hazard. The advent of the sulfa drugs penicillin and other fungus dangers but there is still no substitute for aseptic surgical technique. Stainless steel and vitallium have replaced iron and plain steel and we can no longer use metals which under go erosion or cause electrolytic reactions in the

body tissues. Metallic fixation of fractures has assumed a very important place in bone surgery especially in certain kinds of fractures. The neck of the femur the olecranon process of the ulna, the patella, and the shaft of the tibia may present problems which may legitimately be considered suitable for open operation. Years ago Kellogg Speed in one of these Fracture Orations applied the name 'The Unsolved Fracture' to the very dangerous fracture of the neck of the femur. The medical literature has been full of articles about different methods and devices for the treatment of this lesion. When I was a young man some of the surgeons were using carpenter's screws or nails, with occasional success but with frequent failure. Smith Petersen's three-flanged nail was an enormous improvement over the earlier types, but even today there are clinics where lag-screws, threaded wires, and other devices are preferred to the flanged nail.

Some of the recent publications do not emphasize sufficiently the enormous necessity of accurate reduction of the fracture before it is nailed or screwed. In many of the articles, roentgenograms are shown which reveal imperfect replacement of the fracture before the nail was inserted. This did not always produce a failure of union but it is certainly not desirable and it is usually the result of inadequate x ray control. Anteroposterior x ray films cannot be relied upon to show accurate reduction of the fractured ends and it is extremely difficult to make satisfactory lateral films with the patient's legs fixed firmly in the traction apparatus. No surgeon should attempt to nail a fracture of the neck of the femur unless he can obtain good lateral films on the operating table at all stages of the operation, without disturbing the hip-joint or the operative technique. This means that such patients should be cared for in a hospital with all of the requisite equipment and personnel. It is major surgery of the most difficult type.

The purpose of this lengthy discussion is to emphasize the tremendous importance of developing in every community a team of surgeons who will be able to treat properly the cases of fracture of the neck of the femur and who will have the requisite instruments and

x ray facilities and technicians, without which no one can accurately reduce and nail such fractures. One day in August I examined the x ray films of 3 cases of this kind which had been nailed in other cities. Not one of these fractures had been properly reduced before the nailing and all 3 had failed to unite. It is highly probable that these unfortunate results were due to imperfect lateral x ray films made on the operating table, and I have seen many similar examples, 2 of them occurring in my own practice. Unless the x-ray control is clear and accurate it will be necessary to open the hip-joint in order to be sure that the reduction is satisfactory and that the nail is put in the proper place. This type of open operation adds greatly to the danger of shock and of infection and is practically never necessary when good x ray films are available during the operative procedures.

To make my position perfectly clear the following plan seems to be the best for the treatment of fractures of the neck of the femur.

The patient is placed upon an orthopedic traction table of the Albee, Hawley McKenna, or similar type. The displacement is carefully reduced by the Leadbetter maneuver or by traction. X ray films are made in anteroposterior and lateral planes, one of the two portable tubes being located between the thighs, the other directly over the hip-joint and two or three feet above the field of operation. The perineal post on the sacral support should be of wood or aluminum, so that no manipulation will be necessary for the lateral views. When the reduction is shown to be satisfactory both legs are securely fastened to the traction apparatus. A 5 inch incision is now made to expose the outer surface of the femur and a long wire marked in half inches, is drilled upward and inward from a point well below the trochanter. It is wise to make a hole through the outer cortex with a quarter-inch drill before starting the wire, so that the direction of the wire can more easily be changed without blinding or bending in the thick cortex. When the wire has been inserted to a depth of 3 or $3\frac{1}{4}$ inches, new x-ray films are made to check its position. If not satisfactory the wire is withdrawn and reinserted until it is

in proper position. This may require one or two trials, with corresponding x ray films. A little time may be saved by using another wire, leaving the first in place as a guide. When the position is found to be correct, a cannulated stainless steel or vitallium Smith Petersen nail is threaded upon the wire and is driven along it into the neck and head of the femur. The length of the nail is estimated by the calibrations of the wire. Again x ray films are made in both directions, and if satisfactory the wire is pulled out and the wound closed.

You will see from this description the enormous importance of the x ray examinations, and the complete futility of attempting this kind of operation unless such rapid and accurate roentgenographic control can be furnished. Good anteroposterior views can be made with great ease but the lateral views require special equipment and technique.

I have not mentioned the use of screws, lag screws, or the various threaded or unthreaded wires, because I believe that the Smith Petersen Johansson nail is better than any of them for general use.

A few words about the after treatment. Over the usual dressings a firm, elastic spica bandage should be applied from the waist to the knee, and a foot-piece or sling should be used to prevent outward rotation of the thigh.

It is important to prevent outward rotation of the thigh as the patient lies in bed because the weight of the thigh and leg exert a downward and outward pull upon the nail tending to separate the fragments. It is not wise to allow early sitting and standing without some form of partial immobilization of the affected hip although some writers encourage it.

We must remember that at least 4 months are required for bony union in these cases and that union is made by the internal deposit of new bone, and not by external callus formation.

Aseptic or avascular necrosis of the femoral head is a complication of intracapsular fractures seen less frequently than after dislocations of the hip but nevertheless sufficiently often to influence the ultimate prognosis. The artery in the ligamentum teres supplies only a small portion of the head, and, indeed is some-

times absent. The main blood supply comes from the arteries of the capsule and if these arteries are occluded or are too small the head becomes necrotic. At present, there is no certain means of improving the blood supply although drilling and bone-grafts offer some hope. Perhaps the best form of treatment is to prevent any weight bearing on the femoral head by the use of crutches and a caliper splint, or by long-continued traction trusting that Nature will provide a new blood supply by the slow ingrowth of small arterioles and by creeping substitution. This requires a long time and in some cases fails to occur in which event the patient has a painful and disabled hip-joint which may need a reconstruction operation or an arthrodesis to produce an ankylosis of the joint.

Let us now consider the other types of fractures which may usually be considered suitable for operative treatment. The patella and the olecranon process of the ulna if the fragments are widely separated will unite more satisfactorily and more rapidly if they are mechanically fastened together by one of the accepted operative methods. Spiral or oblique fractures of the shaft of the tibia may be extremely difficult to retain in good position by conservative treatment and it may be wise in such cases, to fix the fragments together by transfixion screws, or even by stainless steel plates. The fibula unites much more rapidly than does the tibia and sometimes holds the fractured surfaces of the tibia so far apart that they cannot unite. Cases of this kind require operation.

For many years the surgical literature has been flooded with articles advocating the use of mechanical devices for the reduction and the fixation of fractures of the long bones. The catalogues of the instrument makers and the published articles of the designers show in fascinating detail the very ingenious devices and the remarkably successful results. The basic principle of all of these contrivances is identical. This principle is to drill two strong pins into the shaft of the bone above the fracture and two more similar pins below the fracture as far away from the fracture itself as possible and to connect each pair of pins with a clamp to hold them rigidly to-

gether. These two units are then used to manipulate the fractured ends into accurate apposition. In difficult cases an ingenious traction frame has been devised to aid in this manipulation. When good position has been attained, the pin units are connected by rods clamped firmly to them, or by short plaster-of-Paris casts molded around the pins. It is not to be denied that this method is very valuable in certain types of fractures. It furnishes good apposition and good control of nearly all types of fractures, and allows early and free movement of the joints at either end of the broken bone. It is, however, neither so simple nor so safe as the inventors and manufacturers would have us believe. It requires considerable skill and experience to drill the pins into the proper positions, whether the pins go entirely through the limb or stop after penetrating both cortices of the bone and project only from one side of the limb. It is also not easy to prevent infection from occurring along the track of the pins, as there is always some seeping discharge from the pin holes, but the advocates of the method state that osteomyelitis is very rare.

The best known of these devices are the Stader, the Haynes, the Griswold and the Roger Anderson types, and of these the Anderson instruments seem to be the most generally satisfactory. They are all modifications and improvements of the old Lambotte ideas, and in a very small proportion of fractures they may be very useful.

Another revival of ancient methods was described by Kuntscher in 1940, who drove a long steel rod into one end of a fractured long bone down through the medullary canal across

the line of fracture. These rods were used chiefly in Germany during the second World War and have achieved some popularity in the United States. One of the advantages of this method is that the broken ends of the bone are pulled into close apposition by the action of the muscles, so that union is much more rapid than when Lane plates are used. The fact that the medullary canal is plugged up by the rod seems to have no deterrent effect upon the union of the fracture.

About thirty years ago Hey Groves treated a fracture of the upper third of the femur in this way using an iron rod, but he complained that the rod was not strong enough to resist the muscle-pull, and so the femur became bent at an angle. If he had put the leg up in a Thomas splint or in plain traction apparatus, after the operation, the result might have been better. With the new stainless steels, the method may be useful in selected cases.

It must be admitted, in discussing the various kinds of operative treatment of simple fractures, that the advent of the sulfa drugs and the fungus derivatives has made open surgery much safer than it was a few years ago, but we must not lose sight of the fact that the majority of fractures can be treated successfully by the older conservative methods. We are going through a transitional period at the present time, both surgically and politically, and I do not want our young physicians impressed with the idea that fracture treatment necessarily means a machine-shop full of tools to repair every kind of broken bone.

The best fracture surgeon uses the fewest gadgets.

THE SURGEON AND HIS TRUST

With Special Reference to Safe Conduct of the Patient through Operation

OWEN H. WANGENSTEEN M.D. F.A.C.S. Minneapolis, Minnesota

THE safe conduct of a patient through operation demands the following (1) adequate preparation of the surgeon (2) careful and precise preparation of the dissection (3) satisfactory preparation of the patient for and adequate care of the patient after operation. All of these items are important. Inasmuch as many of the important items relating to care of the patient before and after operation the subject of this symposium discussion have been dealt with in an eminently satisfactory manner by the other participants I have elected to devote my remarks principally to a somewhat philosophic consideration of the surgeon's own preparation for his responsible tasks. I do not interpret my opportunity of speaking last as affording me the privilege of acting as moderator in this discussion. In the final analysis, you and time are the ultimate arbiters and umpires of what is said here.

THE FUNCTIONS OF SURGERY

The very nature of surgery stamps it as a sacred trust. By general agreement, surgery is invoked only when the desired objective cannot be achieved satisfactorily by non-surgical means. It is the purpose of surgery to preserve life and to restore normal function in so far as is possible and at the least risk to life and without compromise of the patient's future welfare.

FORMALITIES OF SURGERY

Any enterprise which achieves its ends through employment of such extreme means as surgery must of necessity observe certain formalities. In saying this I am not alluding to fatuous conventions and empty ceremonies but to compliance with rules of conduct which

From the Department of Surgery, University of Minnesota Medical School, Minneapolis.
Presented in the symposium on Care of the Patient before and after Operation, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-10, 1946.

time and practice have shown to be valuable guides.

The items listed above which have to do with the safe conduct of a patient through operation are mutually interdependent. One component is unlikely to afford promise of success without the co-operation of the others. A well trained surgeon who comes well prepared for the operation and who performs a superb dissection but who neglects the preparation of his patient before operation or his care after operation is not doing the best for his patient, and the surgeon who bungles the dissection stands in the way of recovery of his patient. Yes, poor preparation of the dissection is alas the agency through which some patients who undergo surgery with the hope of having their lives made happier and longer have them shortened. How poor management of the problem of hemostasis in any type of surgery but particularly in operations involving large blood vessels or performance of an anastomosis in the gastrointestinal canal which is architecturally unsound may shorten the lives of patients needs no elaboration. What surgeon would not prize highly an opportunity to be given a second chance to rectify an error of commission which shortened a patient's life? But an operation like any biological experiment is performed only once. Why not prepare well for it? Death is so final!

Yet, we see surgeons hurrying through operations as though their time were more important than the safety of the patient. Has not the fallacy of the 'get in quick and out quicker' approach to surgical problems been exposed sufficiently? No amount of best care before and after operation can undo the harm of an operation badly performed.

Wise surgical planning limits the surgeon's range of activity. The Army Medical Corps in World War II had a record of accomplishment in the management of difficult surgical problems which was unique in the annals of medi-

cine. The success of that undertaking was the result of planning organization and the selection of individuals with satisfactory training to do a given job. In our own work, we are left largely to our own devices in these matters. The product of our endeavors is dependent in large measure upon how well we have planned and the care with which organizational detail has been carried out. The range of operations which any one surgeon may perform is also a matter of personal choice. This latter item is a matter which demands some standardization among surgeons, just as much as particulars of planning and organization. There are still a few surgeons who affect to believe that they can take all of surgery for their province. They know as well as anyone that their performance in such a wide category of operative procedure is substandard in some of these areas, when judged in the critical light of what constitutes good practice. If a surgeon has not the moral courage to say to himself occasionally "The interests of this patient are served better by having someone more intimately acquainted with the problem undertake this task than I" when will society or medicine set up an advisory group with authority to decide for us that which we have been unable to decide for ourselves?

Even among teachers of surgery who have a better opportunity for continued self-improvement than the rank and file of surgeons, there are still a few who essay to embrace a large portion of all of surgery. In our time, we have seen the province of the general surgeon shrink so much so that occasionally we wonder what areas of surgery are embraced in the designation general surgery. Yet, this is as it should be. If a teacher of surgery were so ardent a student of his art that he wished to encompass the entire field, an aspiration more ambitious than praiseworthy he would remain all his days a learner and would thereby lose the important opportunity to give directional growth to a smaller sphere of surgery. Teachers of surgery must prove themselves in the next generation as well as in this. The teacher who leaves no pupils or intellectual progeny has not been fully alive to his responsibilities or wholly faithful to his trust.

The passing of the all-around surgical specialist. The sprouting of many surgical specialties from the parent stem of general surgery affords some indication of how surgery has grown. Moreover sharper lines of distinction between the various surgical specialties are being drawn. The specialty boards are playing an important rôle in lending acceleration to this transition. In some clinics not so long ago one could see a surgeon, in a single day's work, do a stomach operation or two, a few operations upon the biliary tract, as well as the colon and rectum, and perhaps a few goiters and a breast operation or two in addition and then extend himself into the province of the urologist, gynecologist, and orthopedist. Let us be thankful that the day of the all-around surgical specialist is done! Surgery is not advanced by that type of activity and no matter how talented the surgeon he cannot do equally as good work in all these provinces.

The background of training of the surgeon should be broad. But having acquired orientation and competence, a surgeon must of necessity if he aspires to rise above mediocrity give selective direction to his activity instead of trying to grow in all directions simultaneously. The public has the right to demand a high standard of performance from us. Moreover we are all debtors to our profession and from those of us who have enjoyed opportunities above the ordinary society reasonably may expect that we should strive to add something to the sum total of knowledge rather than continue to be parasites upon our common heritage.

The responsibility of higher institutions of learning to surgery. Surgery has been enriched from many sources. Our institutions of higher learning have a responsibility for leadership in surgical education in this country—not alone to train students for the practice of surgery and to help them meet the requirements of the Specialty Boards, but also for the great task of improving surgery. Recognition of the tremendous importance of research in lending accelerated momentum to the slow growth of knowledge is a part of that responsibility. Knowledge can come to have new meaning with synthesis of well known

facts and much of surgery's progress in the past decade has been compounded out of well known facts becoming known to the right persons. It is to the discovery of new fact however that we look hopefully to the future for significant changes and improvements in surgery that will have the same impact upon our lives as did the discovery of anesthesia and asepsis.

The acquisition of surgical techniques The acquisition of skills is an interesting study. Those of us who have been privileged to be teachers of surgery and who have nurtured young surgical plants have had a unique opportunity to observe how such seedlings grow. Given a good brand of 'plant' with a high native intelligence and a real capacity for application accompanied by an intense and unflagging interest in surgery together with a sympathetic understanding of the frailties of man the capacity for growth of such an individual is almost limitless. And if in addition he is possessed of an inextinguishable yearning to add his bit, whether large or small, to the sum total of surgical knowledge there is no telling how far he may go. That he will surpass his teacher in accomplishment is self-evident. There is a certain inertia or lag in the learning process when progress is made slowly if not almost imperceptibly. But all of a sudden the man who just yesterday seemed almost a novice becomes an accomplished technical surgeon. The circumstances which bring about this accelerated spurt of growth are difficult of assessment and are not readily defined. It is not a process that can be hurried but a development which must come naturally through a certain sequence of events which by no means is the same for all individuals. This development has to do with the surgical neophyte becoming steeped in the practices, techniques and procedures as well as the general approach of a surgical service to problems. In this learning process, acquaintance and an increasing familiarity with the numerous facets of individual surgical problems as they relate themselves to physiology biochemistry or bacteriology are very important. This period of training constitutes essentially an apprenticeship. For the finished surgeon it is a *sine*

qua non. The surgeon who is self taught is distinguished readily from the person who has pursued this more rigorous and orthodox scheme of training. And how quickly the surgeon of ability who has traveled this devious and stony path learns to master the technical phases of difficult operations is always a source of amazement and gratification to me. It is a metamorphosis in which the co-ordination of eye mind and hand are important. The man who can grasp the problem and transmit to his hand what the eye sees and exact from this eye to mind to hand relationship a high standard of performance—that man is the superior surgeon. Before this co-ordination is effected the surgeon seemed but a fledgling but when that time comes almost overnight he becomes an accomplished surgeon whose work reflects confidence in his own performance. Only the surgeon who has trod this steep and winding path can know the cost! Is it worth the effort? Ask any of these men and examine the product critically! Truly there is no royal road to learning.

This circumstance of how quickly the trained surgeon masters operative techniques augurs well for the future of surgery. It suggests how we see further than our predecessors because we stand on their shoulders in turn our students stand on ours. It is a promising prospect for surgery the continued growth of which is assured in the hands of the present keen generation of surgeons who are beginning to make their mark. As Leonardo da Vinci remarked: It is a poor pupil who does not surpass his master.

Motivation of the surgeon One need not gossip long in the medical sewing-circle the confessional in which the sins of our neighbors are confessed more adequately than one's own to learn that surgeons are not generally held in that high esteem by our medical colleagues to which we would aspire. There are those who look upon the surgeon as a manual laborer in a Greek dress. There are even those in our own midst who affect to believe there is less science than art in surgery. And many of our medical colleagues who are not as accustomed or as adept as we in employing their hands in the service of their brains are bold to suggest that surgery is only a trade para-

sitic upon the generous gifts of medicine. Take away the petty skills from most surgeons they say and see what empty sacks remain. Are these critics unmindful of the tremendous impetus given greater medicine by the discovery of anesthesia and antiseptics? Have they forgotten how the ministrations of the surgeon make an important contribution to the daily enjoyment of and in many instances to the extension of life?

It seems to me that trained surgeons schooled in the scientific method hold in their hands important tools by which to push back the boundaries of medical ignorance. A disciplined imagination lies at the bottom of every great discovery. The most important requisite of any promising research project is an idea. Surgeons who aspire to make contributions to the patrimony of knowledge would do well to school themselves in the techniques of one of the biological sciences, such as bacteriology, biochemistry, or physiology. I hold strongly to the belief that for the surgeon who aspires to a career in academic surgery that 2 years spent in acquiring the technique of one of these provinces of knowledge will pay usurious dividends not alone to the individual but to surgery and greater medicine as well.

The author of a recent thought-provoking and deservedly popular book¹ writes, "The surgeon's skill sometimes is a splendid example of the sublimation of an early childhood urge to cut. A well known psychiatrist² wrote a few years back 'Leaving aside all secondary conscious motives for operating other than those provided by reality we realize that much surgery betrays evidences of being uodagruised sadism. I resent such implied or expressed innuendos concerning the motivations of the surgeon. I associate daily with surgeons who give no evidence of such sadistic repressions. If the truth were known the reasons generally are probably far simpler and find their likely explanation in why men become grocers, lawyers, or engineers. You see before you a boy grown to manhood whose consuming ambition was to continue

his activities on the farm that he loved so much. His discerning father suggested that ministering to the physical ills of man would prove even more satisfying than lavishing care on cows, horses and pigs. This was difficult for a growing farm boy to believe. Isasmuch as the spirit of compromise resolves most differences, I suggested veterinary medicine as a substitute. My father far wiser than I continued to insist that medicine was a better outlet, and so I came rather unwillingly into medicine and surgery pushed in through the back door. "Contented industry and the late Wm. J. Mayo, 'is the mainspring of human happiness. And when that labor has to do with making the lot of man more endurable what employment could give greater happiness?' I feel certain that the services of a psychoanalyst need not be enlisted to ferret out the compelling reasons that urged many of you to become surgeons.

It is, however, probably not out of place to suggest that envy because of the relatively larger incomes earned by surgeons and especially by surgical specialists, lies at the root of much of the criticism directed at surgeons by their medical colleagues. On this score I shall only say that for the years that lie ahead surgeons and other medical specialists paid out of proportion to their contribution to the advancement of medical knowledge, as judged from the critical viewpoint of the true scientist, would do well to consider receiving part of their emolument as increased opportunity. Society rewards us generously for our responsible labors in the relief of suffering and the betterment of man's lot. If however, we value even more the approbation of our colleagues with scientific leanings—a consideration which is not unimportant—some thought might well be lent to utilizing partially the potential earning capacity of surgeons as well as that of other highly paid medical specialists to afford ourselves better conditions of work, thereby improving the product of our labor, and at the same time lending a helpful stimulus to surgery. No doubt, many of you already have resolved this problem in some such manner. Satisfactory conditions of work and an opportunity for creative effort are valued by the thoughtful surgeon as among the best

¹ J. L. Lieberman, *Peace of Mind*, p. 28. New York: Ekinon Schuster, 1946.

² Karl Menzinger, *Psychoanal. Quart.*, 234, 5, 173.

of paymasters. No one fears that the successful surgeon will starve! The tissues of the rich and the poor patient present the same problem to the surgeon. And the inarticulate but touching gratitude of a patient who can not pay in the coin of our realm, is nonetheless among the best of all rewards of the surgeon.

The surgeon and particularly the older surgeon will do well to contemplate occasionally his motivations and incentives and revalue anew his rewards. Let him also reaffirm periodically the Hippocratic Oath! When long years ago this writer was confirmed in the faith of his fathers the preacher employed on the occasion a text from the prophet Jeremiah: 'Stand ye in the ways and see, and ask for the old paths, where is the good way and walk therein and ye shall find rest for your souls.' An instruction equally as important for surgeons as well as for Sunday school communicants. Can there be greater rewards than the satisfaction and the peace of mind which come from having served his fellow man well? Our yoke of duty and responsibility may be heavy, but whose opportunity and privilege to bring happiness to others is greater?

The Federated Surgical Society of America
The Regents of the American College of Surgeons provisioned the avid curiosity and thirst for new found knowledge on the part of the practicing surgeon, when they instituted the Forum on Fundamental Surgical Problems. The continued interest in this type of program by the general surgeon in practice affords ample demonstration of the wisdom of that decision. And as more of America's best young surgeons who went to war return and manifest renewed zeal to contribute to the advancement of surgical knowledge an even more critical selection of papers for presentation can be assured. The time is now ripe for the formation of the Federated Surgical Society of America embracing all the ancillary surgical specialties much in the manner of the Federated Biological Societies in the pre-clinical divisions of medicine. That society serves medicine in a unique manner. A similar organization of surgery and its various surgical specialties employing the prototype of the Surgical Forum as its pattern would lend renewed emphasis to the importance of re-

search in surgery. At the same time, it would constitute an important agency in giving better integration to the many now somewhat distinct, branches of surgery. Is not the American College of Surgeons the parent society which should foster this development?

Have surgical meetings had any influence on your intellectual growth and development? They have on mine. Man cannot lift himself up by his bootstraps neither can surgical societies increase surgical knowledge save in so far as they encourage an interchange of ideas between surgeons at the best possible level. Surgical specialists in the same field are not long the best company for one another. There is not enough stimulating sustenance in that type of association for continued growth and development no matter how interesting the interlude provided by such exchanges. The life-giving spirit and vitalizing influence derived from close association with fellow colleagues in the broad domain of medicine is indispensable for the surgeon.

Surgery is on the move. We respect the traditions of the past but the empiricism of surgeons of generations just past is being displaced by the appreciation of and more frequent employment of the scientific method. The touchstone of the scientific method lies in the universal validity of its results. It affords a finality which sets aside all room for continued speculative rationalization. While we are debating and airing our respective opinions on a controversial subject some enterprising individual constructs and carries out the crucial experiment which reveals the truth in the matter. How sterile and unprofitable are discussions based solely on impressions no matter who the authority. Not even the experienced investigator makes a ten strike each time he sets up an experiment. No the progress of research is slow. Yet fact correlated with fact builds a structure which will stand against the winds of time.

It is from the lips of men who are engaged in the exciting pursuit of fact finding that we may expect that stimulating refreshment which makes us better surgeons for the experience. The acquisition of knowledge is not a passive process. List - ing to the recital of the train of events which led up to an im-

portant discovery does not make us better surgeons. It does however make us want to be better and serves to reorient us with reference to the great superiority of the experimental method over empiricism. When all surgeons learn to ask: What is the evidence rather than who employs a certain procedure, then the absorptive capacity of surgeons for new found information will have been enhanced considerably. Surgery will profit immensely by having all surgeons listen to expositions in which the experimental method is employed. Moreover young men prosecuting original researches have a right to be heard. And is it not a bit wearisome to have to listen to parrots of other men's thinking?

Unnecessary surgery. Some of my colleagues who are not surgeons tell me that some surgeons perform unnecessary operations and undertake necessary operations which they are not trained to do for pecuniary gain. This is difficult for me to believe. If there be such men in our profession who call themselves surgeons, God have mercy on their souls! Is not the path of the well trained surgeon intent on doing the very best of which he is capable beset with difficulties enough? Can a surgeon take his tasks so lightly that he would submit patients, who seek his counsel to unnecessary or ill advised operations? God forbid! If this be true every man in the profession every hospital in the land should leave no stone unturned to expose such practice. We who enjoy the greatest confidences of patients who place their trust and lives in our hands have a sacred duty to perform. If we knowingly set aside that trust, we are not entitled to the protection which our medical license gives us.

If I forget thee O Jerusalem let my right hand forget her cunning. Steadfastness of purpose and consecrated devotion to his tasks should characterize the resolution of the surgeon in his outlook upon his work.

Surgery is a stern discipline. Surgery is an exacting and stern discipline. Let no man who aspires to be a surgeon be unmindful of this admonition. A realistic, critical attitude of self-analysis by the surgeon with reference to accountability for operative failures and postoperative complications is a *sine qua non* for continued growth and development of the

surgeon and betterment of his accomplishment. The irrepressible optimism of the Pollyannish surgeon denies him the improvement and cultivation which comes from a critical review of every failure. At the base of most disappointments lie errors in judgment or execution some neglect that might have been prevented with adequate forethought and preparation. Only when surgeons have succeeded in eliminating all avoidable causes of death after operation can they be satisfied with their own accomplishment—a laudable but unattainable objective. Yet, the struggle of striving to achieve that which lies beyond our reach makes us better surgeons for the effort. Any record, in which only unavoidable deaths account solely for the mortality suggests that the surgeon and his associates have done their work well.

Improving the surgical mortality score. A consideration which must be always uppermost in a surgeon's mind is how to reduce the mortality score and at the same time extend the favors of surgery to those patients, who because of age or physical infirmity are not satisfactory operative risks. Familiarity with all the facets of the problem and a studied effort to eliminate or reduce to a minimum all the avoidable causes of death after operation are the items that make for an improved mortality record. In this endeavor the surgeon must exact a high standard of performance from himself as well as from his associates. The day of the one-man operation is over. It takes a trained team of surgeons and nurses, accustomed to working together and alert to the complexities and vagaries of a group of interrelated surgical problems to make a creditable showing. Limitless concern for every detail and precise execution of carefully planned procedures are items out of which success and improvement of the mortality score are compounded.

Preoccupation of mind of the surgeon. Because of the very nature of the cares and heavy responsibilities shared by surgeons, they come to have a certain preoccupation of mind. Try as we may, it is not easy to disguise completely our feelings when vexed with anxieties over ill patients. Those who know us best seem to be able to divine our true state of mind. The

cares of patients weigh heavily upon the mind of the surgeon and it is understandable that his spirits may exhibit some of the fluctuations of a barometer contingent upon how the patients under his care are getting on. Who among us has not felt a certain buoyancy of spirit when a very ill postoperative patient takes a turn for the better?

Static character of surgery made dynamic by synthesis of well known facts into new knowledge This year marks the centenary of the first public demonstration of the employment of anesthesia for operations, one of the most beneficent and welcome gifts to mankind in the history of the world. Antisepsis and asepsis recreated surgery and opened up new and undreamed of avenues for the surgeon's skill. The exclusion of infections from clean wounds gave an impetus to surgery and the entire field of medicine such as it has not experienced since. Surgery bounded forward with a terrific surge. Yet after some years, surgery appeared to have reached an impasse such that, surgeons like the late Lord Moynihan were saying again as surgeons of the preanesthetic and preantiseptic era had said that surgery had reached the acme of its development along technical lines. Yet lesser innovations and a better understanding of the derangements in bodily economy attending operation have remade surgery again. The improvements that have come about in the last decade or more are not the startling variety that marked the swift progress which came with anesthesia and asepsis. Nevertheless, real improvement in many areas of surgery is readily discernible. The greatest forward strides probably have been made in intrathoracic surgery. Improved techniques in this province of surgery have permitted performance of operative procedures with low mortality rates for conditions which surgeons looked upon with bopeless discouragement and despair a generation ago. Vascular surgery of the thorax is a new chapter in operations being written by the surgeon of today who has schooled himself in the stern discipline of preparing nice dissections of the large blood vessels of the thorax.

The gauge of a surgeon's accomplishment must be measured against the achievement

for that period. It is unfair to compare the performance of a surgeon of one generation with that of another. There were good surgeons 25 years ago but surgical organization in well appointed hospitals is much better today. Anesthesia is considerably better, our understanding of the nutritional requirements of surgical patients is far better and our knowledge of care of patients before, during and after operation is better. Nursing care also is considerably better than it was a generation ago. We know more about shock and replace blood loss more adequately. We have learned that it takes time and patience to do operations well and that maintenance of a steady state of the patient throughout the operative procedure has done away with the necessity for hurry a circumstance which condemned many an operation to failure although the advocates of the method continued to insist it was the chief determinant in deciding whether a patient would survive.

In other chapters of surgery there has been less conspicuous but nevertheless noticeable improvement. Gastrointestinal surgery has been quite static for a generation. Yet, with similar improvements in technique which gave such accelerated momentum to the surgery of intrathoracic conditions, the last few years also have witnessed the extension of operations upon the gastrointestinal canal to older age groups and standard risk patients with a constantly declining mortality rate. Apart from the items listed above which played so important a rôle in the flowering of intrathoracic surgery an additional factor which has been of particular significance for the improvement of results in abdominal surgery has been increasing appreciation of the importance of suction applied to duodenal tubes to obviate the occurrence of intestinal distention following operation. Moreover prevention of gastric retention precludes regurgitation into the lungs a former frequent cause of postoperative pneumonia.

The discovery of the sulfonamides and penicillin has lent a great impetus to surgery as it has to medicine as a whole. The discovery of a new fact can change the whole complexion of a problem. But how plodding a process is the discovery of a single new fact!

Fig. 1. Weighing scale employed in the general surgical operating rooms at the University of Minnesota Hospitals. Such a scale weighs to an accuracy of 1 gram. The use of dry sponges (save on exposed viscera such as small bowel or lung) serves to inform the surgeon of the blood loss at any juncture of the operation.

Little wonder that a new fact is a priceless possession and that we immortalize the names of men who have added a single important fact to knowledge. Keener appreciation of previously known facts lends its stimulus to a branch of knowledge the impact of a new fact, however gives impetus and momentum that is felt over a tremendous range a new fact is like a ferment in changing a static state into a dynamic one. It breathes new life into an undertaking.

FORTUNES OF SURGERY

There is no equation or formula which can give a complete answer to the important question of what may be expected of an operation.

Fig. 3. Use of the Red-cross litter on platform for patients who can not stand. This scheme of weighing needs the help of nurses and an orderly to lift the patient, with least discomfort to him, onto the litter. (Surg. Gyn. Obst., 94 Feb. 2A)

Fig. 2. Patients undergoing difficult operations on stand on a bedside weighing scale the day following operation. Patients are weighed in the morning before and rounds, the gain or loss in weight from the prospective weight helps to determine the water and sodium chloride requirements for the next 24 hour period.

The planning of the procedure, the nature of the organization in which the surgeon works, his training and his general outlook on his responsibilities, the character of the dissection he performs, the breadth of his comprehension of what constitutes satisfactory preoperative preparation and postoperative care and the vigilance with which the anesthetists, the surgeon and his staff and the nursing staff watch over the patient—these are the determinants of the outcome of an operation. And yet even in this enumeration some things are left to chance. On this latter score, may I say that the surgeon who leaves the care of a number of items to chance is an unsafe surgeon. No matter how well we have standardized the performance of a certain operative procedure, they are not all performed alike. The hemostasis in one operation may not be as satisfactory as we may have wished it or the somewhat irregular placement of a single suture may have angulated an anastomosis whether gastrointestinal or vascular such as

Fig. 4. a. A new bedside weighing scale built for me by Mr. John A. Phelan of the scientific apparatus shop. This scale, with an electrically driven motor to hoist the patient up and let him down permits weighing the patient in bed.

b. The scale in use. The hoisting device lifts the patient a few inches off the bed. There is no interruption of the administration of intravenously administered fluids.

to affect its function unfavorably. The performance of surgery demands a high level of concentration together with a harmonious co-ordination of eye hand and mind. Perhaps it was this circumstance that Thomas Fuller had in mind when he said the surgeon stands in need of an eagle's eye a lady's hand and a lion's heart. For the difficult surgery of today a sturdy pair of legs is also an indispensable necessity!

Fatigue undermines the surgeon's efficiency
There is no effective antidote for the fatigue and weariness which beset the surgeon in long and strenuous operative ordeals. Intentness of purpose urges him on to the performance of his best effort though it cannot drive away the subjective feeling of fatigue and the physical impairment of efficiency which comes with long sustained application under trying circumstances. There are operations being performed now of such magnitude that the surgeon occasionally stands in greater need of postoperative treatment than the patient on completion of the operation! It is my feeling that an impetus may be lent to the safe conduct of patients through some of the more difficult and tedious operations, when university clinics come to attach greater importance

to some of the techniques employed by industry and football coaches in combatting the inefficiency of fatigue by sending in a fresh team. No surgeon of experience will deny the deterioration of accomplishment which attends fatigue. The interests of the patient which should be the paramount concern in any operation would be served better by such an expedient.

The great need of more precision techniques
Surgery and surgeons generally stand in serious need of greater precision techniques in the gauging of patients as satisfactory risks for operation in the assessment of whether the preoperative preparation is adequate in the intricacies of the operation as well as in post operative management. There is a mortality and morbidity of treatment as well as of disease! Let no surgeon mistake this. We are prone to say the patient died despite all our efforts. How often the converse is true the patient died because of what was done. Are we so blind or dull that we cannot see this? It is in the critical analysis of the events leading to unhappy outcomes that surgeons have the opportunity to improve themselves and to improve surgery.

We can all point out in our own experiences the repercussive effects of ill advised treatment. In this connection I like to tell undergraduate students of an experience in which I was in a manner a participant. My family has a summer home not far from the Twin Cities. One of my neighbors is a veterinarian.

One summer before the long war years, we both had young dogs. My good friend the veterinarian said to me his dog had manifested a few signs of distemper and he was in the process of vaccinating him for it. Being a good neighbor he volunteered to do as much for mine. I decided to let my dog take his chances with the distemper. He did contract it and was ill for a week or so but made a complete and satisfactory recovery. A short time following our initial conversation I asked the veterinarian how his dog was getting on. He said he feared he had overdone the vaccination of his dog and in consequence the dog's appetite was poor. As a stimulus to appetite, he was giving the dog some strychnine and the dog was showing signs of improvement. A week later our paths crossed again and I asked the doctor how the dog was getting along. He said that the dog had been overtreated with strychnine causing him to have convulsions. In an effort to control the convulsions, he had anesthetized the dog with ether and had given him too much ether and had killed him! We too are guilty of occasionally shortening lives when we are striving to make them longer and happier. And often that rôle is not as self-evident as it was in this story.

How many patients lose their lives each year because of mismanagement of the water and electrolyte requirement of patients? To say many is an understatement. Is it happening in your clinic? It has in ours. I believe that when surgeons generally become more alert to the factors of safety in this intricate problem they will have taken an important step forward in improving their own accomplishments. I shall not say very much about our general plan of management of this problem here for I have discussed the problem at length elsewhere (2, 3, 4). I have the feeling however that when surgeons lend a more attentive ear to assessing such needs of patients in a more quantitative manner they will be agreeably surprised to observe what great help such guides afford them.

Routine use of dry sponges in operations affords an opportunity to assess the gain in weight, thus informing the surgeon of the extent of the blood loss at any juncture of the

procedure. To replace fluids in kind and in amount with that lost is obviously the best treatment. And to weigh patients before and immediately after operation as well as in the convalescent period is the best of all guides in helping the surgeon orient himself with reference to the electrolyte and fluid requirements of his patient. Moreover the weighing scale is far more sensitive in the detection of minor changes in body hydration than are changes in hemoglobin. Obviously such routine weighing of patients undergoing major surgery is often unnecessary for the problem of hydration seems to resolve itself by employment of simpler means involving less trouble constituting therefore needless effort. But who counts the cost of labor when lives are at stake? Do we not read almost daily in the newspapers of the heroic sacrifices of men with no view to cost or personal danger, assuming large risks in the effort to save a life? In the hospital in which you work have lives not been lost because the surgeon and his staff were not alert to the changes occurring in hydration and electrolyte balance of the patients? We have lost patients needlessly through this agency while professing an interest in the problem of water and electrolyte requirements of postoperative patients, at the same time, enlisting the helpful co-operation of the best talent that a University Clinic has to offer in the solution of such problems. It is in just such situations that the weighing scale has its chief virtue, in affording a preview of what will happen if abnormal contractions or increases in body weight continue uncorrected. This I may also say since the expedient of weighing patients undergoing major surgery has become routine practice on the writer's surgical service, loss of life through disorientation of the surgical staff with reference to the important problem of hydration of patients has been more than decimated. I must confess we still go astray occasionally but usually recognize the error of our ways before disaster overtakes us. It is in the surgery of elderly substandard risk patients, who tolerate abuses poorly and especially in the surgery of gastrointestinal conditions necessitating the presence of intubated duodenal tubes, that the weighing scale is a

sine qua non if the surgeon aspires to do such operations with risks not far out of line with those assumed by younger standard risk patients. Reducing the mortality score as I stated previously consists essentially in the recognition of error and its correction. If a patient's weight in the early postoperative phase can be maintained within 2 to 3 per cent of the preoperative value (plus or minus) the surgeon is assured that the water and electrolyte requirements of his patient are being met satisfactorily. Pneumonia and cardiac failure as a consequence of overhydration owing largely to the administration of too much sodium chloride we saw not infrequently postoperatively among older patients undergoing extensive and complicated surgery before routine employment of the weighing scale. Routine weighing of such patients to detect deviations from the preoperative normal is at least as important as taking the patient's temperature. When surgeons learn to deal satisfactorily with the difficult problem of hydration of postoperative surgical patients, one of the most formidable of hazards to safe conduct of the patient through operation will have been surmounted. It is a barrier to recovery from operation that the surgeon must learn to hurdle.

Mr Albert Sullivan Jr.¹ in studying the case records of 151 consecutive patients undergoing major surgery upon the gastrointestinal canal, during the first 6 months of 1946 observed that in this group slight losses of weight were far more common than gains in weight. Only 11 patients (7.3 per cent) showed a weight gain of 2.5 per cent of their total body weight, whereas 76.8 per cent exhibited weight losses of 2.5 per cent or more. The greater number of this group lost weight during the first 5 days after operation. Only 1 patient lost more than 6 per cent of the body weight. The average age in this group of patients was 58.9 years. These findings suggest that our surgical staff is more sensitive to weight gains than losses in weight. All of the patients in this group had intubating duodenal tubes, presenting therefore essentially the most difficult problems of maintenance of

water and electrolyte equilibrium. Obviously the cause of the weight loss in most instances was administration of too little sodium chloride accompanied by employment of moderately generous quantities of 10 per cent glucose solution. The effect of such therapy is to promote diuresis a circumstance that is pleasing to surgeons especially when dealing with a group of patients whose mean age is high. Needless to say it is important to take careful note of small deviations from the preoperative weight in order to keep fluctuations in weight at a minimum. Of the total measurable output of body fluid 70 per cent was the remainder being constituted largely by the fluid aspirated by the intubating duodenal tube. The average daily administration of sodium chloride was 6.5 grams in the early convalescence of those patients losing 2.5 per cent or more of their body weight. These observations suggest that the daily administration of 6.5 grams of sodium chloride is probably slightly less than enough for patients with intubating duodenal tubes undergoing major surgery upon the gastrointestinal canal.

Acquaintance with and employment of precision techniques by the surgeon and his staff in the various items that hedge about an operation afford the patient the best promise of a favorable outcome. It is the operation without mishap and a convalescence without complication that spells success. Such a procedure also permits early ambulation and early dismissal from the hospital. The convalescence punctuated by complication is synonymous with increased morbidity as well as mortality. The circumstances which characterize success and failure are often 'minor differences' but it is out of infinite and alert attention to detail that success is compounded. By very dint of relentless perseverance in his attack upon the factors that constitute the "minor differences" between success and failure the surgeon can gradually overcome the hazards that are undermining his efforts. Recognition of error when accompanied by a resolute determination shared by the surgeon's staff to avoid the repetition of such mistakes, is the best assurance against failure. It is a source of never recurring wonder to me how well patients get on after serious operations un-

¹Medical student from Tulane, doing a voluntary externship on the surgical wards during the summer of 1946.

attended by complication. And when surgeons succeed in making the unpleasant trials of the waking and recovery periods following operation more agreeable, patients will be less likely to regard an operation as a journey through the valley of the shadow of death.

SUMMARY AND CONCLUSIONS

Order is heaven's first law. It also must rank among the most important of guiding principles in the surgeon's code. Without order the results of operation are unpredictable. A surgeon who has regulated his activity in accord with semblance of good order comes well prepared for operation. Preparation has to do with readiness as well as fitness. He does not undertake operations for which he is not prepared. Nor does he perform unnecessary operations. The surgeon's trust is as sacred as life itself and must not be profaned. The surgeon who has schooled himself in the preparation of nice and precise anatomical dissections does not permit himself to be hurried. He places the safety of his patient above every other consideration. And the security of the patient demands not alone that, the surgeon watch over him with tender and observant care during operation but that the surgeon has seen to it that no detail is overlooked in the preoperative preparation, and that alertness and vigilance characterize the care of the patient after operation.

The success of operations depends upon a harmonious blend of many things. The practical wisdom garnered from experience is in

essence an issue resulting from detection, acknowledgment, and correction of error. Though we falter if we are in earnest in our determination not to fail, success is inevitable. We must learn to count the cost less and value the result more. The surgeon's objective should be the elimination of all avoidable causes of death after operation. The safe conduct of the patient through operation is a matter upon which an instruction can be given more readily than consistently followed. Portia's prudent counsel in the *Merchant of Venice* on this score is well known to you. She said, "If to do were as easy as to know what were good to do, chapels had been churches and poor men's cottages princes' palaces. It is a good thing that follows his own instructions. I can easily teach twenty what were good to be done than be one of the twenty to follow more men teaching. The fortunes of our patients are determined by the manner in which the formalities of surgery are heeded by the surgeon. The functions of surgery and its future growth as a benevolent and helpful aid to man suggest that improvement in accomplishment demands that the surgeon be mindful and observant of the stern disciplines of his handicraft.

CLINICAL USES OF STREPTOMYCIN IN MEDICINE AND SURGERY

H CORWIN HINSHAW M.D. Rochester Minnesota

ALTHOUGH streptomycin was first described by Schatz, Bugic and Waksman less than 3 years ago the drug is already in full commercial production and distribution and has proved to be a useful antibacterial agent in medical and surgical practice. The full possibilities and limitations of streptomycin treatment in several important diseases remain to be determined but progress has been extremely rapid in the last 2 years and should continue at an accelerated rate.

The usefulness of streptomycin is dependent on the fact that this antibiotic agent is effective against several pathogenic bacteria which are not susceptible to the action of other antibacterial substances. These bacteria include some frequently encountered gram negative bacilli and above all the bacillus of tuberculosis.

The treatment of infections of the urinary tract due to bacteria sensitive to streptomycin has been extensively studied (7-9) and it is uniformly agreed that streptomycin is of value in such treatment although its potentialities are limited. These bacteria frequently acquire a resistance to the action of streptomycin within a few days hence if permanent results are to be realized, it is extremely important that conditions favorable to persistence or recurrence of infection be corrected promptly if possible. Strains resistant to streptomycin are more likely to be developed if there is obstruction to flow of urine or if calculi or other anatomic defects permitting survival of bacteria are present. The importance of proper timing of treatment in relation to surgical intervention becomes obvious.

Bacteremia due to gram negative bacilli sometimes occurs, especially in association with severe infections of the urinary tract and

as a postoperative complication following operation on the infected urinary tract. Streptomycin therapy frequently is effective in treatment of such bacteremia (7-9) when due to organisms sensitive to this antibiotic agent (9).

Meningitis due to sensitive micro-organisms especially gram negative bacilli should be treated with streptomycin utilizing both parenteral and intrathecal routes of administration. My associates and others (7, 9, 10) have reported favorable results in influenza meningitis treated with streptomycin.

Since acute peritonitis is frequently of such serious portent and due to such an admixture of pathogenic micro-organisms I would recommend the simultaneous use of all available antibacterial agents in medical treatment. The combination of streptomycin with penicillin appears to be thoroughly logical under these circumstances, especially if the peritoneal cavity is soiled with intestinal contents.

Wound infections due to mixed bacterial flora should frequently be treated with both penicillin and streptomycin especially if bacteriologic examination proves the presence of sensitive micro-organisms. Fully adequate debridement should first be carried out to minimize the possibility of a recurrence of the infection due to bacteria which have acquired a resistance to the action of streptomycin.

Streptomycin is of real value in some cases of chronic suppurative pulmonary disease such as bronchiectasis (11) and especially as a preoperative measure preparatory to pulmonary resection. Here again it should usually be used in conjunction with penicillin and administered as an aerosol. The duration of treatment will vary from 1 to 2 weeks or more the treatment being continued until sputum is reduced in amount, changed in character and rendered bacteriologically sterile or nearly so. Cases of bronchiectasis suitable for streptomycin therapy may be selected by merely ex-

aming smears of the sputum stained by Gram's method. If numerous gram-negative bacilli are present, streptomycin is likely to be a useful adjuvant to penicillin therapy.

Acute and chronic infections of the respiratory tract due to organisms of the *Hemophilus* and *Klebsiella* groups may be treated successfully with streptomycin (7-9).

The treatment of tularemia with streptomycin has yielded spectacular and promptly curative results (5). Streptomycin may be considered a specific remedy for tularemia; hence the accurate diagnosis of tularemia becomes of greatly increased importance.

Brucellosis and typhoid fever are caused by organisms which are only moderately sensitive to streptomycin. The latest available reports of streptomycin therapy in these diseases are not encouraging (9) except possibly during the most acute phases with demonstrable bacteremia.

When streptomycin is administered orally it is not absorbed from the alimentary tract in significant amounts; hence its oral administration is useless for treatment of systemic infections. However the antibiotic agent is not destroyed but remains within the lumen of the bowel to exert its antibacterial effect on the intestinal flora (6). The possibilities of orally administered streptomycin have not been fully studied for preoperative preparation of patients prior to intestinal operation, either as a substitute for sulfonamides or in combination with sulfonamides. My surgical colleagues have made sufficient use of streptomycin in this manner to indicate that it does have practical possibilities.

The action of streptomycin on cultures of *Mycobacterium tuberculosis* was noted early (13) but this is a property which had been described previously for a number of other substances of microbial origin (4) and many synthetic chemical compounds (14). When streptomycin proved to be extremely effective against experimental tuberculosis of guinea pigs (2-3) its clinical possibilities were recognized and quickly explored.

The greatest potentialities for streptomycin therapy appear to exist in treatment of tuberculosis (8) including some surgical types of tuberculous infection. This is due to the fact

that no other practical and effective antibacterial therapy is available against the bacilli of tuberculosis and to the fact that this bacillus is much more sensitive to streptomycin than are the other common pathogenic bacteria. Furthermore the tubercle bacillus remains sensitive to streptomycin for at least a few months before becoming drug resistant (15) and this permits realization of satisfactory therapeutic effects, especially in lesions of recent origin. It also has been found that some rather poor candidates for radical surgical treatment of pulmonary tuberculosis may be rendered excellent candidates after a few months of treatment with streptomycin. Likewise postoperative tuberculous complications may be amenable to streptomycin therapy or may be prevented by use of the drug.

Many types of tuberculous infection unfortunately produce destructive changes which no drug can directly benefit. Antibacterial therapy is only suppressive in this and other diseases and will yield permanent benefit only if natural mechanisms of healing can achieve supremacy during the limited period of a few months during which the bacilli are sensitive to the action of streptomycin. Selection of tuberculous patients for streptomycin treatment must be undertaken with the greatest care. During the past a year my colleagues and I have followed a few simple rules, based on our concept of the action of streptomycin. These rules may be enumerated as follows: (1) Patients who are making satisfactory progress on conventional forms of treatment for pulmonary tuberculosis or who are likely to do so should not receive streptomycin. (2) Patients who have terminal types of pulmonary tuberculosis, especially when bilateral destructive changes are present, and who could not become candidates for surgical treatment are not regarded as good subjects for streptomycin treatment. (3) Patients who have old chronic nonprogressive fibrocavensous and cavernous types of pulmonary tuberculosis are not likely to experience satisfactory results and hence should not be treated. (4) Priority in treatment has been given to more acute, progressive pulmonary tuberculosis of recent origin. In general, patients with most severe constitutional symptoms and with least destructive

pulmonary changes have obtained the best results from streptomycin treatment. These are individuals with naturally low resistance or with depleted resistance, and hence those most in need of assistance from antibacterial therapy. It should be repeated that such treatment should be given before the disease has wrought changes in the lung such as cannot be repaired within a few months. All patients with pulmonary tuberculosis chosen for streptomycin treatment should have a component of exudative disease and the larger the proportion of exudative to proliferative tuberculosis the better.

The clinical results of treatment of such patients often are realized promptly. Within the first few weeks fever declines, cough and expectoration decrease, appetite and a sense of well being return and the patient begins to regain lost weight. Later after 6 to 8 weeks of treatment, roentgenographic evidences of improvement of exudative lesions are first noted. Usually within 3 to 5 months maximal clinical and roentgenographic improvement has been attained. This would appear to be the time for surgical treatment of remaining disease and especially for closure of any remaining cavities, such as might serve as sources for subsequent bronchogenic dissemination of the disease.

Ulcerating tuberculous lesions of the larynx, the hypopharynx and the tracheobronchial tree have healed rapidly and so far without exception in our small series of 10 cases. These patients have received combined treatment with intramuscularly administered streptomycin and streptomycin aerosol.

Some types of extrapulmonary tuberculosis have responded to streptomycin treatment with remarkable uniformity. This is especially true of chronic long standing draining sinus tracts, which usually close within a few weeks, but these will remain closed only if treatment is continued for several weeks after apparent healing. In renal tuberculosis and tuberculous cystitis temporary and palliative effects have been observed frequently but actual healing of renal lesions has been observed rarely possibly because the kidney lacks the power to heal tuberculosis readily. In only a few cases of tuberculosis of bones and joints has strepto-

mycin been used but results have been encouraging. Much remains to be learned about streptomycin in relation to orthopedic surgery in the treatment of tuberculosis of the skeletal system.

Until the advent of streptomycin there was no way in which the course of tuberculous meningitis and miliary tuberculosis could be modified. Even with streptomycin treatment there is an extremely high mortality rate. However in most cases of early tuberculous meningitis the patients respond promptly to adequate intramuscular and intrathecal streptomycin treatment but all too frequently these gains are not permanently sustained. At least temporary clinical remission is almost the rule following streptomycin treatment of early but acute and severe tuberculous meningitis. Consciousness is regained often within a few days fever declines within a few weeks a sense of well being returns and frequently patients appear to be essentially normal, even for several months. Subsequent exacerbations of the disease are likely to recur and not to respond to treatment. However this may not always be true for in 3 cases of proved tuberculous meningitis arrest of the disease continued for several months following discontinuation of a 6-month course of intensive treatment. One patient has no residual neurologic signs, one is normal except for deafness and the third has apparently received severe damage to the central nervous system, especially the cerebellum. Although nearly a year has passed since the onset of illness in these 3 cases it is too early to classify the patients as cured. Five patients who had tuberculous meningitis have died despite treatment but 3 of these did not receive what is now regarded as adequate treatment and the remaining two were first seen at a late stage of the disease.

Disseminated hematogenous tuberculosis of miliary type has not responded previously to any form of treatment and spontaneous recoveries have been extremely rare. With streptomycin treatment it is possible to bring about a complete clinical and roentgenographic remission in a large proportion of cases but unfortunately the recurrence rate has been very high thus far and three of our four treated patients have eventually died. The remaining

patient has remained well for 6 months but cannot yet be classified as cured.

Tuberculosis of the alimentary tract and tuberculous peritonitis have not been studied adequately but symptomatic improvement of the 5 patients who have been treated at the Mayo Clinic has been striking.

Although clinical effectiveness of streptomycin is readily demonstrated in many types of tuberculous infection the results are often not permanent and frequently do not compare with results achieved in acute diseases treated with other antibacterial agents such as penicillin. The limitations of streptomycin treatment in tuberculosis must be emphasized constantly in this day of miracle drugs and the emphasis must still be placed on the known effective methods of treating tuberculosis, especially care in a sanatorium and collapse therapy. The place of streptomycin in tuberculosis therapy has not been determined but this agent is much more likely to supplement than to supplant the proved effective standard methods of treatment.

Streptomycin usually is administered by intramuscular injection doses being given every 3 to 4 hours and totaling from 1 to 3 grams per day. The lower limits of effective dosage have not been fully explored nor can final statements be made concerning the upper limits of safe dosage. Streptomycin is more toxic than penicillin but very little difficulty is experienced in treatment of more acute diseases which require only a week or two of treatment. When treatment is continued beyond 3 to 4 weeks nearly all patients will experience some disturbance of equilibrium (1) occasionally to a severe degree. Fortunately compensation is achieved in all or nearly all instances more promptly in younger than in older patients and no permanent disability is likely to result. Sluggish response to caloric stimulation of the vestibular apparatus is usually noted for many months and perhaps permanently even when there is no residual functional disability. The cause and significance of these changes have not been determined fully and are in need of complete investigation. Deafness has been noted occasionally but hearing is ordinarily regained if treatment is discontinued promptly. In this respect, strep-

tomycin resembles such drugs as quinine and salicylates. Evidence of renal limitation has been noted occasionally but serious renal damage is not nearly so likely to occur as it is with administration of sulfadiazine. Streptomycin should be used with caution when there is reason to fear pre-existing impaired renal function because the drug may not be readily excreted under these conditions.

SUMMARY

Streptomycin is an effective antibacterial remedy of value in treatment of several infectious diseases not amenable to treatment with other antibacterial substances.

Streptomycin may be used in combination with penicillin for treatment of mixed infections such as are likely to occur in the presence of acute peritonitis, chronic suppurative pulmonary disease and contaminated wounds.

Streptomycin has value in treatment of infections due to gram-negative bacteria occurring in the blood stream, in the meninges, or in the urinary tract.

Streptomycin is highly specific in treatment of tularemia. It has but little value in treatment of brucellosis and typhoid fever.

Streptomycin is the only practical antitubercular substance which is useful in treatment of tuberculosis. Limitations of streptomycin therapy in this disease appear to be imposed by the destructive and granulomatous changes produced in tuberculous tissue and by the fact that the drug cannot be depended on to destroy tubercle bacilli in the human body.

THIOURACIL AND IODINE

The Preoperative Management of the Thyrotoxic Patient

BENJAMIN GOLDMAN B.Sc., M.D. F.A.C.S., JAMES D. WEAVER, M.D. and
E. M. RALSTON A.B. M.S. Ph.D. M.D., Erie, Pennsylvania

FROM the reported experiences in the collected literature, 3 salient characteristics of thiouracil therapy have been emphasized. These have been the prompt clinical response to the drug, the standardization of the dosage at 0.6 gram daily by which the basal metabolic rate is reduced 1 per cent each day and most important, that thiouracil toxicity has appeared in about 14 per cent of all patients so treated. Since so much value yet so much danger has been found in the treatment of the thyrotoxic patient with thiouracil, some safer method of management should be sought to obtain the maximal therapeutic effect of the drug with the greatest margin of safety. This has been the objective of the present study: an admittedly small series since from a total experience of 527 thyroidectomies only 20 recent hospital cases were considered suitable for this form of therapy.

There were 16 females and 4 males varying in age from 23 to 76 years. The average age of 45.1 years was equivalent to that of 190 thiouracil-treated patients reported by Labeyrie. In the series were 9 nodular and 9 diffuse goiters and 1 recurrent goiter in each group. The tissue submitted from the recurrent diffuse goiter was reported by the pathologist as adenocarcinoma. All admission basal met-

abolic tests were made after at least one day of rest in bed. The highest was plus 72.4 per cent and the lowest plus 25.1 per cent. The average plus 43.57 per cent. This approximated Lahey's average of plus 49 per cent. Admission leucocyte counts ranged from 10,050 to 41,500 with an average of 7,135. All other clinical laboratory determinations and radiological examinations were performed routinely on admission but have been omitted from this report. Medication was withheld until the laboratory findings were charted. Bed rest except for 2 hours daily was the rule. In addition ice caps were applied to the head and precordium intravenous fluids were administered as indicated and sedation obtained by the generous use of phenobarbital. The average daily dose of phenobarbital was 4 grains. This included the larger doses of 3 grains to 9 grains given the night before operation. While the Bartlett's have advocated larger amounts to produce narcosis and semi-anesthesia these patients were easily managed on the smaller dosages since avertin was used as a basal anesthetic 45 minutes before the scheduled operating time. All patients received 0.6 gram of thiouracil daily divided into 3 doses each of 0.2 gram. The longest period of administration was 21 days the shortest 6 days and the average 11.9 days. There were 4 exceptions to this dosage. In 3 patients it was necessary to increase the amount and in 1 to decrease it. In Case 8 patient previously iodine resistant, required 0.6 gram daily for 8 days 0.8

6.2 days. Thyroidectomy was performed without incident and without postoperative storm in all cases. In Case 5 a large nodular intrathoracic goiter in a patient aged 65, the admission basal rate was plus 31.3 per cent and grave myocardial damage without heart failure was present. The rate was reduced to plus 14.2 per cent by thiouracil and patient was then iodinated. Death occurred less than 30 minutes after the incision was made as the right lobe and isthmus were removed. This was a cardiac death in the thyrocardiac group which is known to carry the highest mortality rate.

Since end results and the time spent in a hospital have always been pertinent factors in this form of management should be compared with present methods of combined ambulatory and hospital care. Thiouracil was used an average of 11.9 days plus Lugol's solution 6.2 days or a total preoperative time of 18.1 days. Case 5, the operative death and Case 20 in which patient refused operation have been deducted from these figures. The average postoperative time was 6.8 days or an average total hospitalization of 24.9 days. During all of this time each patient was under medical control while receiving a known toxic drug. This control cannot be exercised over outpatients having at their personal disposal 1 or 2 weeks supply of thiouracil. Until thyroid disease can be cured medically, the thyrotoxic patient must eventually come to operation. While the standard 0.6 gram daily dose of thiouracil effectively reduced the basal metabolic rate this small series of 527 thyroidectomies and the thousands re-

ported elsewhere have clearly pointed out that Lugol's solution, bed rest and sedation as well as thiouracil are still factors essential to the successful management of the thyrotoxic patient.

SUMMARY AND CONCLUSIONS

1. Thiouracil has a field of usefulness and should be limited to the preoperative preparation of the thyrotoxic patient.

2. The dangers which have been previously reported appear to be due to the prolonged use of a potent drug.

3. These dangers can be minimized in the hospital by careful observation, study and the individualizing of treatment to the needs of each patient.

4. It would seem unwise to place in the hands of an out patient a dangerous drug and allow such a patient to be removed from regular and controlled observation.

5. The use of iodine in conjunction with thiouracil is a sound and safe practice since it eliminates uncontrollable operative hemorrhage and thus ensures safe hemostasis.

6. Reduction of the basal metabolic rate to limits between plus 15 per cent and plus 30 per cent by thiouracil followed by the administration of large doses of iodine reduces the preoperative preparation time to the economic advantage of the patient without materially increasing the surgical risk.

TABLE II.—CLASSIFICATION OF CLINICAL DISORDERS OF FLUID AND ELECTROLYTE BALANCE*

Water disequilibria	Salt disequilibria
1. Acute water deficit.	1. Extracellular salt water deficit.
2. Chronic water deficit.	2. Extracellular salt water deficit with water deficit.
3. Absolute water excess.	3. Extracellular salt water deficit with relative water excess.
	4. Extracellular salt water excess.
	5. Extracellular salt water excess with relative water deficit.
	6. Extracellular salt water distributional shifts.
	7. Any of above (1, 2, 3, 4, 5, 6) with changes in base-bicarbonate (alkalosis or acidosis)

*Intracellular salt disequilibrium states are not considered in constructing this table.

gresses at a rate rapid enough to prevent the kidney from excreting salt in sufficient amounts to maintain the solute concentration of the body fluids at a normal level. This state is accompanied by intense thirst if the individual is conscious. The clinical signs that accompany acute water deficit are oliguria, dryness of mucous membranes, elevation of body temperature (rectal), and hallucinations, disorientation mania, and coma in order of progression of the deficit. The laboratory signs are a high urine specific gravity (if renal function is good) high blood urea, and concentration of red blood cells plasma proteins, chloride and sodium in the blood.¹ The correlatives necessary for making the diagnosis are the physical signs of water deficit, a high urine specific gravity and the absence of signs of an extracellular salt water volume deficit (see extracellular salt water volume deficit)

Chronic water deficit. (Primary water deficit with a normal solute concentration of body fluids, Fig. 2.) Chronic water deficit is the most frequently encountered disturbance of fluid equilibrium in psychiatric institutions. It differs from acute water deficit because a compensatory renal excretion of salts (Na and

Fig. 2. At left, normal extracellular fluid at night, chronic water deficit.

K) occurs as the body content of water falls (4). This tends to maintain the solute concentration of body fluids within normal limits. However, salt concentrations finally rise when the deficit of water becomes so great that in sufficient water is provided to the kidney to excrete the salt necessary to keep solute concentrations normal.

In the treatment of chronic water deficit one must remember that salt deficit is associated with the water deficit even though no obvious loss of salt by vomiting, diarrhea, or sweating has occurred.

The cause of chronic water deficit is a decrease in the rate of water accretion of such a degree that the rate of total water gain is less than the rate of minimal water loss. However, the discrepancy between the gain and the loss of water is not so great as to prevent the kidney from holding the solute concentrations of body fluids within the ranges compatible with health.

The most frequent cause of the disorder is a reduction in the sensorium that under conditions of health keeps the water content of the body within a relatively narrow range of variation. Its frequency of occurrence is high in psychopathic states organic brain disease (senile alcoholic, luetic, postapoplectic), drug addiction, chronic febrile illnesses, geographic limitation of water intake, and chronic painful states (peripheral vascular disease, causalgia, chronic infection, arthritis and neoplasia).

The clinical signs of chronic water deficit are predominantly those of an extracellular salt water (base) deficit provided that the development of the deficit proceeds slowly enough for the kidney to keep the solute concentration of the body fluids constant. However the signs of acute water deficit may be added to those of extracellular salt water defi-

¹N is especially that diminished elasticity of the skin, softening of the eyeballs, and longitudinal wrinkling of the tongue are not listed as signs of acute water deficit.

MOYER FLUID AND ELECTROLYTE BALANCE

erally associated with states of water deficit or excess, or states of alkalosis or acidosis. A continued excretion of sodium in excess of that taken into the body is its cause. The excretion may be extrarenal (vomiting, diarrhea, fistula) or renal. The renal excretion may be compensatory as in chronic water deficit or pathologic as in renal tubular hypofunction (hydro-nephrotic atrophy). The associated presence of water equilibrium disturbances will depend upon the concomitant rate of water accretion. If less water is drunk during the development of the extracellular salt water deficit than was lost through kidney, skin and lung, an associated deficit will be present. The development of changes in composition, alkalosis or acidosis, are mainly dependent upon the composition of the fluid lost from the body. Polyuric obstruction with vomiting of an acid solution tends to be associated with an alkalosis. Loss of pancreatic juice, an alkaline solution (pancreatic fistula), produces acidosis.

The signs and symptoms of an extracellular salt water deficit are variable. They depend in part upon the rate of formation of the deficit, upon the water content of the body other than that in the extracellular fluid, upon the concomitant rate of potassium loss, and upon the degree of the "uncompensated" compositional changes that may be associated with the deficit. The signs and symptoms of a relatively uncomplicated deficit are as follows:

1. Usually there are no definite signs or symptoms associated with a salt water deficit of 0 to 2 per cent B in a healthy adult.¹ However, in the aged in winter and in the chronically ill, a reduction of the extracellular salt water volume of this degree may be attended by severe symptoms and signs.

2. An extracellular salt water volume decrease of 2 to 4 per cent² B is accompanied by apathy, weakness, somnolence, anorexia, brief periods of nausea, reduced affective responses,³ transient vertigo on assuming the erect posture, a soft pulse with insignificant

and variable changes in systolic blood pressure and pulse rate, and a slightly sticky skin. This stage has been called the "early barbituric acid-depressive phase of salt deficiency."

3. An extracellular salt water volume decrease of 4 to 6 per cent B ($1\frac{1}{3}$ to $1\frac{1}{2}$) of the extracellular fluid volume is associated with an increase in severity of the above signs and symptoms and in addition occasional unproductive retching, syncope on attempting to stand, a lowered blood pressure—frequently to "shock" levels, a variable pulse rate—usually tachycardia, a subnormal temperature if ambient temperature is below 85°F,⁴ a wrinkled tongue, sticky skin, "putty" muscles, and soft eyeballs.

4. Coma finally supervenes and death occurs with reductions of the extracellular salt water volume of $\frac{1}{2}$ to $\frac{1}{3}$ of the "normal."

The laboratory signs are variable and are in part dependent upon the amount of the deficit (little change of solute concentration with small deficits regardless of rate of water ingestion) (1) upon the composition of the salt solution excreted (plasma chloride falls faster if stomach contents are lost than if small bowel contents are) upon the rate of water accretion in deficits of salt water volume greater than 2 to 3 per cent B (see chronic water deficit and extracellular salt water deficit with "relative water excess") and upon the rate of development of the deficit.

The finding of "normal" blood solute or red blood cell concentrations does not rule out the presence of an extracellular salt deficit. However, a diminution of the solute concentration (Na and Cl) with an increase in the concentration of red blood cells (high hematocrit) is positive evidence that a relatively severe and rapidly developed extracellular salt water deficit exists. The relationship of the changes in solute and red blood cell concentrations to the salt water deficit are qualitative but usually not quantitative. Therefore the history and the physical examination constitute the best bases for ascertainment of the existence of salt water deficit.

B—original body weight.

¹When extracellular salt water volume deficits are very small, a proportionately greater water deficit, when they are great and the individual is near death, when it occurs in infancy or when it is incurred in hot climates, an elevated temperature is usually found.

²The more rapidly the deficit develops, the more severe are the symptoms and signs that accompany a given deficit.

³Author's observations on C.A.M. Three trials, fasting state for 14 hours, volume deficit induced by continuous duodenal drainage for 50 hours excepting for eight 14-hour periods when the tube clamped to permit the drinking of water to allay severe thirst.

⁴No desire to smoke, read the paper or talk to anyone.

Theoretically the actual water content of the body in this state, although it is usually in deficit, may actually be in excess of the individual's usual content in health even though extracellular fluid volume is below normal in spite of its dilution with water. To have this particular condition readily obtain it is necessary that the loss of extracellular sodium proceed without much reduction of intracellular base and with a rate of water accretion that is faster than its rate of loss.

A full blown picture of an extracellular salt water deficit with water intoxication does not occur often with environmental temperatures below 85 degrees F. However at low environmental temperatures it may complicate the course of recovery from trauma (operative, 20 thermal 22, crush) provided that too much water is given too soon or that too little sodium is given too late. The rate of excretion of positive loads of water by the kidney is reduced and may approach zero with severe salt water deficits. In oliguric or anuric states associated with an extracellular salt water deficit, the restoration of the solute volume and the concentration of the extracellular fluids by the administration of an appropriate interstitial salt solution is of primary importance in the re-establishment of kidney function. If an attempt be made to force urine flow by the administration of water before the extracellular fluid volume deficit is corrected, severe water intoxication may be induced, and an oliguria converted to anuria.

Extracellular salt water deficit with water excess (miner's cramps) occurs fairly frequently in hot environments if a sodium deficit is incurred while the drinking or the administration of water is not limited (21). Heavy work by an untrained, unacclimatized person (high rate of Na loss through sweating) and a reduction of sodium intake below minimal rate of loss in a person at rest (alcoholism, febrile illnesses, etc.) are the usual immediate causes of the sodium deficit.

through fistulous tracts (duodenal, choledochal, pancreatic and enteric); with the chronic loss of extracellular fluid from granulating wounds; and with inattention to details in the care of people with large wounds (placing individuals with large open wounds or granulating surfaces in tubs of water rather than on lin, the covering of large wounds with wet dressings that are wet with water or hypotonic salt solutions as boric acid).

The physical signs and symptoms of an extracellular salt water deficit with relative water excess are those of an extracellular salt water deficit, those of an absolute water excess, and those of uncompensated compositional changes if they are present. Obviously large individual variations in signs and symptoms will be present. The laboratory signs of an extracellular salt water deficit with relative water excess are as follows: a low sum of the plasma chloride and bicarbonate (below 115 to 120 mEq per liter) in the absence of acetoneuria, a low urine chloride concentration and a normal or an increased concentration of red blood cells. These are the most essential correlates to be considered in formulating a diagnosis of an extracellular salt water deficit with relative water excess.

Extracellular salt water excess (Fig. 7) The symptoms and signs of a rapidly induced relatively small excess are listed in Table III. The sensible loads at the end of the period of loading varied from 2.8 to 4.1 percent of body weight because of the excretion of the salt water (renal and intestinal) that occurred during the loading period. The volume of

Fig. 7. At left, normal extracellular fluid; at right, extracellular salt water excess.

fluid given always amounted to 5 per cent body weight in 5 hours.

The signs and symptoms vary and seem to be partially dependent upon the composition and toxicity of the solution that was administered especially by the oral route. Haldane and Priestley described this relationship earlier. The salt solution drunk "was meant to approximate to the salt content of human serum and was found to be much more palatable than 6 p.c. sodium chloride solution—a point of some practical importance because it

Group. Nine healthy fasting men, loaded with 5 per cent B_u of .85 per cent NaCl solution at rate of per cent B_u per hour by mouth.

Group. Five healthy fasting men, loaded with 5 per cent B_u of .85 per cent interstitial salt solution ($NaCl$, 14 mEq. per liter plus $NaHCO_3$, 30 mEq. per liter in water) at rate of per cent B_u per hour by mouth.

Group 5. Five healthy fasting men, loaded intravenously with 5 per cent B_u of .85 per cent NaCl solution at rate of per cent B_u per hour (.85% $NaCl$ is 5% glucose solution produced more severe post-administrational muscular incoordination).

Group 4. Five healthy fasting men, loaded with 5 per cent B_u of .0.6 per cent $NaCl$ solution (rate of per cent B_u per hour by mouth).

was found to be almost impossible to drink rapidly two or three litres of sodium chloride solution without producing vomiting' (17)

Hoarseness and a sensation of 'heavy eyelids' are the only constant symptoms associated with a sensible load of 2.8 to 4.1 per cent body weight of the above solutions. Greater positive loads of salt solutions are associated with the gross collection of fluid in subcutaneous tissue, in body cavities and in some organs. Therefore gross overloads of 15 to 25 per cent body weight are associated with variable signs and symptoms that have an intimate relationship to the degree and rate of impairment of breathing, circulation and renal function.

Extracellular salt water excess rarely exists without a disturbance in the content of water in the body in relation to total solutes. A relative water deficit is commonly associated with it. This state is described below.

Extracellular salt water excess with relative water deficit (Fig. 8). This syndrome may be readily induced during the postoperative period and after trauma by the exclusive use of an isotonic salt solution to provide for the water and salt needs of a person who cannot

Fig. 8. At left, normal extracellular fluid, at right, extracellular salt water excess with water deficit.

eat or drink. It is physiologically analogous to the illness induced by drinking sea water to satisfy thirst.

If 0.9 per cent sodium chloride solution (159 mEq. sodium per liter) is the only fluid infused into healthy fasting men the urine excreted during the first 24 hours does not contain much more sodium than the infusate per unit volume. Consequently the amount of water made available to the body from the saline solution is smaller than the insensible loss of water and the concentration of salt in body fluids increases.

If the intravenous injection of 0.9 per cent sodium chloride in water or 0.9 per cent sodium chloride in 5 per cent glucose into a healthy man is continued at a constant rate during the next 24 hours so that an amount of solution roughly in excess of 3 per cent of body weight is administered in 24 hours, a new equilibrium state tends to be established. This state is characterized by the excretion of the salt given that day and by a concentration of sodium chloride in the urine sufficiently greater than its concentration in the infusate so that enough water is thereby provided to balance the insensible loss, and the concentration of salt in the body remains at the level reached

the previous day or it decreases. If the above solutions are given as the sole source of water during renal insufficiency states or during the immediate postoperative period when the kidneys' ability to excrete sodium in high concentrations in the urine is limited, a much greater excess of sodium chloride and a greater deficit of water in relation to total body solutes will exist before the new equilibrium state is reached. Indirect evidence indicates that under certain circumstances the relative water deficit may reach such proportions as to be associated with anuria in the presence of edema. The syndrome of "acute salt intolerance" is now thought to be due to salt excess with a relative water deficit.

The symptoms and signs are as follows: disorientation, anorexia, nausea, vomiting, a diminishing rate of urinary flow in relation to the amount of fluid retained, hoarseness, and the collection of fluid subcutaneously, in the lungs, and in body cavities. The plasma sodium concentration tends to be elevated, and the red blood cell count and plasma protein concentration tend to be reduced. If oliguria is present, the nonprotein nitrogen of blood increases.

Changes in composition of extracellular fluid (Departure from the normal electrolytic pattern of extracellular salt water) Changes in the composition of extracellular fluid can be of many types. A few of them are hypoproteinemia, hyperproteinemia, hypocalcemia, hypercalcemia, hypochloremia, hyperchloremia, and acidosis, alkalosis. Only two of them, acidosis and alkalosis of nonrespiratory origin, will be considered.

The degree of acidosis or alkalosis present should be looked upon as a measure of the organism's inability to compensate for a change in the relationship of the bicarbonate ion to the anions of stronger acids (SO_4 , HPO_4 , Cl , lactate) in the extracellular salt water. In other words, the actual change in the hydron concentration (acidosis or alkalosis) is a measure of the effectiveness of the respiration, the renal function, and the buffer systems to compensate for an alteration in the relationship of acid (H_2CO_3) to base bicarbonate (HCO_3)—HA/BA. This change in relationship in the type of acidosis or alkalosis con-

sidered here is due to a shift in the proportion of HCO_3 to the sum of the other anions of stronger acids than H_2CO_3 in the extracellular fluid (Cl , HPO_4 , SO_4 , lactic and other organic acids).

The signs and symptoms of a relatively uncomplicated¹ base-bicarbonate deficit ("acidosis") and of a base-bicarbonate excess ("alkalosis") are relatively mild. The reduction by one-half² of the base bicarbonate (to 10–14 mEq per liter) by drinking hydrochloric acid is attended by moderate dyspnea and hyperpnea with mild exercise, such as walking at one's usual rate on level ground and severe dyspnea after rapidly climbing three flights of stairs similar to that which may be experienced during the last 50 yards of the "440". There is no appreciable dyspnea or sense of fatigue at rest, but recovery of a feeling of well being after exercise is long delayed with the above base-bicarbonate deficit. No great change in the mental reactivity was noted at the above level of base bicarbonate deficit. Greater noncompensatory deficits of base bicarbonate to one-quarter of normal (7–8 mEq per liter) in adults (13) and to less than one-fifth of normal (4–5 mEq per liter) in children (13) may not be attended by any grossly detectable signs or symptoms indicating an impairment of the function of the central nervous system.

Similarly, the elevation of base bicarbonate to 40 to 52 miliequivalents per liter of plasma (CO_2 combining capacity 90 to 120 volumes per cent) may not be associated with any detectable mental or physical signs of illness, even the tendency to the development of muscular cramps and hyperexcitability of tendon reflexes may not be apparent. Hypopnea is difficult of detection without actual measurement of the minute volume of respiration. Therefore it appears that most of the symptoms usually ascribed to "acidosis" (base-bicarbonate deficit)³ and "alkalosis" (base-bicarbonate excess) are the result of the concomit

¹Acidosis—rapidly induced by drinking N/100 hydrochloric acid.

²Alkalosis—rapidly induced by drinking 33 per cent NaHCO_3 in water.

³Disorientation, anorexia, nausea, vomiting, weakness, apathy, pain in muscles, paralytic ileus, hypotension, fast pulse.

ant disturbances in physiologic components other than base bicarbonate. Fagge in 1874 (9) first called attention to the apparent rôle played by dehydration (salt water deficit) in the clinical picture of diabetic coma and to the partial efficacy of the injection of a saline solution into the blood. However following Stadelmann's implication of acid poisoning as the cause of diabetic coma, the rôle of the salt water volume deficit in the picture of diabetic coma was largely forgotten for a time.

Within the last two decades Fagge's original ideas have been rediscovered, and it is now realized that salt water deficits (extracellular

($\text{Na}^+ \text{Cl}^- \text{HCO}_3^-$) and intracellular ($\text{K}^+ \text{HPO}_4^{--}$) may quite frequently accompany nonrespiratory base bicarbonate deficits and base bicarbonate excesses. Consequently as more experience is gained in treating individuals suffering from disturbances in body fluid equilibrium, it is realized that the symptoms and signs of severe alkalosis or acidosis, with their ubiquitous physiologic effects, may be minimal and that it should be more generally realized that the direction of one's efforts toward their correction without taking cognizance of the relatively large neutral salt water deficits that are associated with them will occasionally result in inadequate salt water replacement. Then the signs and symptoms ordinarily ascribed to the alkalosis or acidosis, excepting those related to respiration and in the case of alkalosis those relating to ionized calcium deficit, may persist though to a lesser degree after the carbon dioxide combining capacity has been returned to normal. Therefore, in the treatment of a base-bicarbonate excess or deficit the replacement of the attendant neutral salt water deficit should always be kept in mind. See Table IV for the treatment of acidosis and alkalosis.

Extracellular salt water distributional shifts (Fig. 9) (Reciprocal variations in the extracellular salt water volume of various tissues, with the total extracellular salt water volume of the body remaining constant.) This type of disturbance in fluid equilibrium is frequently seen by the surgeon. Varying degrees thereof universally accompany all trauma. The experiments of Underhill, Kapsinow and Fiske

Fig. 9. Extracellular distributional shift from torso to lower extremities.

(23) demonstrated that the rate of shift of fluid into an injured area is rapid and that after the fluid has entered the injured area, it does not leave it in appreciable amounts for 50 to 70 hours. The increment of fluid in the injured area actually constitutes a functional loss of salt water and plasma proteins from the body (the uninjured part). Red blood cells also collect in the injured tissue largely because of the capillary dilatation and the static flow of blood in it. This constitutes a functional hemorrhage although the total red cell volume remains within normal limits as determined indirectly from the hematocrit and plasma volume determinations or directly using carbon monoxide.

A distributional shift of body fluids following trauma is similar to an uncomplicated extracellular salt water deficit or a chronic water deficit. Clinically significant distributional shifts of body fluids are associated with trauma (mechanical, e.g. crushing injuries, fractures of the pelvis and femora; major operative procedures; thermal e.g. scald and burn and chemical, e.g. peritonitis following perforation of the duodenum or gall bladder) with thrombophlebitis with infections such as gas gangrene, typhus fever and trichinosis and with toxic dermatoses. This list is not complete.

Salt water (see Table IV distributional shift) blood and plasma protein constitute the basic therapeutic elements in the treatment of distributional shifts of body fluids.

More detailed and specific directions for the treatment of disturbances in the equilibrium of body fluids than those included in this paper can be found in the *Journal of the American Medical Association* (3) and in the *New England Journal of Medicine* (1).

MOYER FLUID AND ELECTROLYTE BALANCE

TABLE IV—TREATMENT OUTLINE

Fluid volume state	Repair solution	Concentration of solute in repair solution	Composition of repair solutions		
			Compositional change in extracellular fluid		Alkali excess (Minimal—moderate)
			Alkali normal	Alkali deficit (Minimal—moderate)	
Acute water deficit	Glucose in water	5, 10, or 15%	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride. Ratio Na Cl : NaHCO_3 : KCl mEq 4 : 1.0 : 0.66		Sodium chloride
Chronic water deficit	Sodium salts	100 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride. Ratio Na Cl : NaHCO_3 : KCl mEq 4 : 1.0 : 0.66		Sodium chloride
Extracellular salt water deficit with water deficit	Sodium salts	150 to 350 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride. Ratio Na Cl : NaHCO_3 : KCl mEq 4 : 1.0 : 0.66		Sodium chloride
Water excess	Sodium salts	150 to 250 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride. Ratio Na Cl : NaHCO_3 : KCl mEq 4 : 1.0 : 0.66		Sodium chloride
Extracellular salt water deficit with relative water excess	Sodium salts	60 to 100 mEq/liter	Sodium chloride plus sodium bicarbonate (or lactate) plus potassium chloride. Ratio Na Cl : NaHCO_3 : KCl mEq 4 : 1 : 0.66		Sodium chloride
Extracellular salt water distributional shifts	Glucose in water	10 to 15%			

Extracellular salt water excess with or without a relative water deficit

When distributed fluid volume states exist with severe compositional disturbances, the initial treatment should be directed toward the correction of the fluid volume state. In the treatment of NaCl or a 0.9 per cent solution of NaCl are effective. In the treatment of severe extracellular salt water deficit with water deficit, the initial treatment should be directed toward the correction of the fluid volume state. In the treatment of severe extracellular salt water deficit with water deficit, the initial treatment should be directed toward the correction of the fluid volume state.

tually increase as an extracellular salt water volume deficit occurs as a result of pancreatic or biliary drainage, and it may be below normal when the extracellular fluid volume is normal (hypochloremia secondary to a primary carbon dioxide excess as in emphysema, asthma, depression of breathing by opiates) or when the extracellular salt water volume is even greater than normal (hypochloremia secondary to an excess of water as in water intoxication).

The weight of the body from day to day is not an universally sound physiologic basis for the determination of the salt and water needs of the individual. Distributional shifts of extracellular salt water into the subcutaneous tissues or into serous cavities occasionally occur rapidly and as a result thereof the rest of the body suffers from the depletion of its extracellular salt water—there is need for salt water even though the individual's weight has not changed. Conversely an individual who has been given salt water or plasma in the treatment of injury (burns) usually begins to lose weight rapidly between the fourth and seventh days as the edema of the burned area subsides. Salt water should not then be given to the patient even though he is losing weight because he is excreting the salt that was given to him while the edema was forming and now that the edema is subsiding the salt constitutes an excess. If one assumes that except for the above types of illnesses, weight change is a sound basis for controlling fluid administration he assumes that the ideal water and salt contents of the body are constant. This is likely not true though only a small amount of exploratory research work has been done on the possible changes in the "ideal" body content of water and salt associated with various ills. Under certain circumstances the "ideal" water and salt contents of the body may be larger and under others smaller than they are in the healthy individual.

When determinations of the volumes of plasma and extracellular salt water can be made easily and repeatedly they may become valuable aids in the diagnosis and treatment of disturbances in body fluid equilibrium.

"Ideal" contents may be defined as those most conducive to the rapid recovery of health.

Changes in the concentration of plasma solutes and red blood cells are most valuable as checks of the appropriateness of the diagnosis and treatment.

Because there are no simple dependable means of detecting small extracellular salt water deficits, the daily parenteral administration of salt to those who cannot eat or drink is presumably an expedient that should be employed even though no salt is being lost through extrarenal channels or sequestered in diverse regions of the body. How much salt should be given under these circumstances?

Because healthy nonfasting men habitually eat 2 to 10 grams of salt daily it has been felt that a sick man who cannot eat should receive parenterally at least 5 grams a day in order to maintain his salt balance.¹ However men suffer no apparent harm if their salt intakes are reduced to 1 gram daily. The Tlascalan Indians forgot the taste and the use of salt after they had been cut off from salt for centuries (16). Infants sustain their most rapid period of growth on about a gram of sodium chloride per diem.

It appears likely that the salt that man ingests daily is dictated by taste and habit rather than by actual need, and that healthy men in general have within their bodies more salt than is actually necessary for the maintenance of health. Quantitative salt excretion studies lend support to this idea. The question of the optimal salt intake, during a fast, is still unanswered. From a surgical standpoint, the routine parenteral administration of 5 to 9 grams of salt daily when there is no abnormal functional loss thereof is in certain instances capable of delaying recovery. In fact, a slight deficit of extracellular salt water may be preferable to any excess (even 5 to 9 grams daily) especially during the immediate postoperative period. This belief is supported by a number of reasons.

1. For 2 to 4 days after any injury injected salt solutions tend to collect most rapidly and to a relatively greater extent in the area of injury (19). This phenomenon is very easily demonstrated in anyone upon whom a colostomy has been performed. If no saline is given the transudation from the surface of the loop will be relatively small and it swells

MOYER FLUID AND ELECTROLYTE BALANCE

relatively little, if then 2,000 cubic centimeters of 0.9 per cent saline solution are administered, the transudation and swelling increase rapidly. An enteric anastomosis behaves in the same way, the edema that occurs about the region of the anastomosis is greater if saline is given. Therefore, the resumption of the normal continuity of the intestine following an enterocenterostomy or enterocolostomy will tend to be longer delayed as the amount of salt injected is increased. On one occasion an edematous occlusion of a gastrojejunostomy stoma was found to be the cause of a complete gastrojejunal obstruction 24 days after a subtotal gastric resection. The mass of salt given daily was 4 grams over that lost as gastric drainage. No subcutaneous edema was present. Following the second operation, although no corrective operative procedure was carried out, the functional patency of the anastomosis was established after 4 days of a zero intake of salt. The rate of healing of wounds tends to be related inversely to the local edema; the greater the edema, the slower is the rate of healing. This is most clearly demonstrated in the experiments performed by Glen, Gilbert and Drinker.

2 The incidence of postoperative pulmonary complications after upper abdominal operations is higher especially in the aged when maintenance doses (5 to 9 grams daily) are in excess of those given in the younger. The rate of healing of wounds tends to be related inversely to the local edema; the greater the edema, the slower is the rate of healing. This is most clearly demonstrated in the experiments performed by Glen, Gilbert and Drinker.

3 A deficit of extracellular salt water is more easily corrected than an excess.

The adoption of the policy of withholding salt during the immediate postoperative period until signs of its need appear shifts the responsibility for the maintenance of a physiologically adequate extracellular salt water volume from the kidneys of the patient to his physician. This responsibility is big. If signs of illness are present or appear after an operation or injury that are attributable to a functional extracellular salt water deficit contracted by an external loss or an internal shift thereof, vigorous saline therapy must be instituted and the consequences of local edema forgotten.

If there are indications for the parenteral administration of fluids, what solution or solutions should be employed? In general the

solution used should be so composed as to effect the return to normal of the various deformations of the body's fluids without producing other deformations that may be more difficult of accommodation by the organism than the original ones were. Obviously, if the kidneys of all sick individuals would perform as do those of healthy men the manufacture of a universally applicable repair solution would be feasible, in fact 0.9 per cent sodium chloride in water or in 5 per cent glucose (glucose-saline) could serve in that capacity.

If a water deficit existed, it could be corrected by the administration of 0.9 per cent sodium chloride in amounts in excess of 3,000 cubic centimeters daily, should the kidney excrete urine that contained 1.8 per cent salt, for then all the salt injected could be excreted in one-half the volume of water that was injected as 0.9 per cent salt, thus making available to the body a volume of water equal to the volume of urine.

If a water excess existed and the kidney excreted the sodium chloride in 0.9 per cent concentration or lower the water content of the body would decrease by an amount equal to or greater than the insensible loss of water.

If alkalosis existed, the excess of chloride relative to sodium in the 0.9 per cent sodium chloride solution, compared to the concentration of chloride relative to sodium in plasma would serve to reduce the alkalosis (the concentration of alkali) even should the kidneys put out no urine. If acidosis was present, the administration of 0.9 per cent sodium chloride would permit its correction if the kidneys were capable of excreting sufficiently greater amounts of chloride than sodium.

However, the kidneys of men and women who have been injured or operated upon are relatively unable to excrete a urine having a higher concentration of sodium chloride in it than is present in 0.9 per cent sodium chloride, and consequently water deficits tend to be increased rather than alleviated by the administration of 0.9 per cent sodium chloride solution. In addition, the kidney's ability to excrete chloride in excess of sodium is reduced following trauma or an operation, and therefore the correction of an acidosis with sodium chloride may be impossible.

In other words, solutions of 0.9 per cent sodium chloride in water or in 5 per cent glucose (glucose-saline) are not universally applicable repair solutions because the renal function tends to be depressed following operations and trauma. Therefore, the solutions employed in the correction of fluid disequilibrium states should be so constituted as to effect the correction without depending upon the kidneys.

The solutions that fit the physiologic requirement for the correction of the fluid disequilibrium states described herein are listed in Table IV.

The volume of fluid administered and the rate of administration depend largely upon the response of the individual and the constitutional severity of the depletion.¹ Usually the volume of salt solution given in 24 hours should not exceed 6 per cent of the weight of the body unless the rate of functional loss of extracellular salt water continues at a rapid rate, either as a result of the continuance of distributional shifts (burns, trauma, peritonitis, gas gangrene) or as a result of continued high rates of external loss (ileostomy, colostomy or other fistulous drainage). Under these latter conditions the infusion of salt water may have to be continued to 10 to 15 per cent of the weight of the body per 24 hours. When a rapid rate of infusion is employed or a large volume of fluid is given repeated auscultation of the chest and gross determination of venous pressure should be performed. If rales appear or if the veins of the neck become distended and tense the infusion should be temporarily discontinued.

After the correction of deficits has been effected, the amount of salt water given daily will depend upon the continued existence of the cause of the deficit. If the cause of the deficit is a distributional shift due to an injury the movement of extracellular fluid into the injured part will tend to decrease rapidly so that after 36 hours there will be little further shift. After 72 to 100 (23) hours have elapsed after the injury the extracellular fluid in the injured part will begin moving back

into the rest of the body and no more salt should be given because a functional excess of extracellular salt water then exists. If the loss of extracellular salt water continues (because of hyposthenemic nephropathy, fistulous drainage, diarrhea, vomiting, gastroduodenal drainage) the loss of salt should be made up, as it occurs, by the injection of a saline solution that has the salt compositional pattern of the body fluid lost.² (See Gamble for the composition of various body fluids.) If no salt is lost after the correction of the deficit, very little if any need be given.

Another general physiologic principle that should be kept in mind when one prescribes parenteral fluids is: A primary change in the body's content of one substance is associated with changes in the organism's content of other substances consequently the restitution to normal of the primary change in content does not insure the restitution to normal of the secondary changes upon which the ultimate recovery of the person may rest. For example a man who excretes large amounts of hydrochloric acid into his stomach, develops pyloric obstruction and vomits a large amount of chloride and a smaller amount of sodium are lost in the vomitus. This increases the concentration of base-bicarbonate in the body and the pH of the extracellular fluid increases, respiration slows and the amount of carbon dioxide in the body increases, base-bicarbonate is excreted through the kidney and the body's content of base and consequently of extracellular salt water are thereby diminished. Sodium enters the cells of the body (6) and potassium leaves them to be excreted; a deficit of potassium is incurred thereby. The volumes of plasma and of extravascular extracellular salt water decrease, plasma protein leaves the blood stream (8) and the total circulating protein falls although none is lost externally. The red cell mass actually declines although the hematocrit may rise (14).

Now let the extracellular salt water volume deficit be replaced by the infusion of 0.9 per

¹Man with extracellular salt water depletion associated with signs of "shock" receives more solution 1. faster rate than those having extracellular salt water depletion without signs of "shock."

²Small, give NaCl 45 to 60 per cent, gastric drainage with free hydrochloric acid in it, give NaCl 45 to 6 per cent; hyposthenemic nephropathy and enterostomy drainage (ileostomy or long-tube section) give NaCl plus NaHCO_3 plus KCl (see Table IV), pancreatic fistula, give osmotically equivalent amount of NaCl plus NaHCO_3 (5 grams NaCl plus 4 grams NaHCO_3 per liter).

MOYER FLUID AND ELECTROLYTE BALANCE

cent sodium chloride solution the chloride and sodium deficits and a part of the carbon dioxide and base-bicarbonate excesses are relieved. There still exists a deficit of plasma protein, a deficit of red blood cells, and an intracellular potassium deficit and sodium excess. (The chemical signs of an intracellular potassium deficit are a persistently high carbon dioxide combining capacity, a high blood urea (or non protein nitrogen), and a low chloride concentration in plasma [4].) If an attempt is made to "correct" the high carbon dioxide combining power and the "hypochlor emia" by further administration of sodium chloride, the deficit of potassium tends to be aggravated regardless of whether the chloride is retained or excreted and the chloride concentration of plasma remains low and the carbon dioxide combining power high.

Therefore, it is obvious that the infusion of sodium salts alone will not satisfy the physiologic demands of the organism after reconstitution of the extracellular salt water volume and that the transfusion of whole blood and the administration of potassium salts should be considered as integral parts of the treatment of a large salt water deficit (7) especially if it has developed slowly and is associated with pronounced physical signs such as great weakness atonic muscles and hypotension. Upon theoretical (10) and clinical grounds the transfusion of blood should be withheld until partial reconstitution of the extracellular volume has been effected in order to minimize the tendency for the intravascular agglutination of red blood cells and clotting. Darrow (4 to 7) has demonstrated recently that a deficit of potassium frequently accompanies disturbances of extracellular fluid equilibrium and that it has great physiologic and clinical significance.

SUMMARY

A clinical plan is presented for the recognition of disturbances in the equilibrium of body fluids.

The disturbances in equilibrium considered are (1) acute water deficit (2) chronic water deficit (3) absolute water excess (4) extracellular salt water deficit, uncomplicated (5) extracellular salt water deficit with water deficit

(6) extracellular salt water deficit with water excess (7) extracellular salt water excess (8) extracellular salt water excess with water deficit, (9) changes in composition of extracellular fluids (electrolytic pattern) (10) distributional shifts of extracellular salt water.

The general principles of therapy involved are

1. It is better to treat the man than it is to treat his "blood chemistry," plasma proteins hematocrit, or weight. A presumptive clinical understanding of the types of disturbances in the equilibrium of body fluids may be gained from a correlation of the history and the physical examination of the patient. The laboratory data are valuable as checks of the diagnosis and treatment, but they should not be used as primary bases for either

2. Sodium salts should be given when they are needed and should be withheld when they are not.

3. A primary change in one physiologic variable, such as the sodium content of the body is attended by secondary changes in other physiologic variables, consequently, the reconstitution of the primary variable to "normal" content does not insure the return to normal of the secondary variables upon which ultimate recovery may rest. Decreases in the volume of circulating red blood cells and plasma proteins and in the mass of intracellular potassium are important secondary variables associated with sodium deficiency, especially if the sodium deficit has developed slowly.

4. The kidneys of patients treated by the surgeon are often not "alert" enough to alter a 0.9 per cent solution of sodium chloride to appropriately balanced salt solutions should be used.

USE OF BLOOD AND BLOOD SUBSTITUTES

JOHN D STEWART AB MD Buffalo New York

IN recent years much new information regarding the nature origin and function of different elements of the blood has become available through the researches of biochemists physiologists and clinicians. In many instances the clinical applicability of such information has been obvious and the patient has derived immediate benefit. In this field as elsewhere in medicine progress in the care of the sick depends not only on the fundamental contributions from laboratories of basic science but on the clinician's alert and intelligent appraisal of new facts and on his skilful application of these new facts in the clinic.

Whipple and his collaborators have done much to define the facts of protein metabolism and the conditions governing the regeneration of the plasma proteins and hemoglobin (10 14 15). The quality and quantity of protein ingested the state of the liver the presence or absence of infection or intoxications, the factor of individual organismal variation and the availability of iron to the body have been shown to be critical conditions in the maintenance of normal hemoglobin and plasma protein concentrations and blood volume. They have shown that the healthy animal for example can replace all its circulating plasma protein in 3 days under the stimulus of plasma withdrawal while taking a protein rich diet. Hemoglobin which contributes six times as much protein to the blood as does plasma protein takes about six times as long for replacement. Body protein accretion (both new hemoglobin and tissue protein) is believed to go through the transition stage of plasma protein. The protein of the plasma thus constitutes a pool which is drawn upon by the cells throughout the body and which is in constant interchange with cell protein. The studies of

Schoenheimer and others using tagged elements supports the conception of continual and rapid movement of amino acids through out the proteins of the body. The blood then must be regarded as a tissue which is in dynamic equilibrium with the other tissues of the body and its composition and volume are maintained relatively constant only through a set of remarkably complex and continuous reactions.

Of particular interest to surgeons also is the work of Cohn and his group in the fractionation and characterization of the plasma proteins (3 4 9). As methods have been developed for the separation of the different proteins of the plasma it has become possible to prepare them for tests of their function with a consequent better understanding of the physiological rôle of the individual fractions. The properties of the different fractions are of great clinical importance, and must be considered in the intelligent use of blood and blood substitutes. For example the colloid osmotic force of plasma proteins is essential to the maintenance of the volume of the circulating blood and when the plasma protein concentration falls below a so-called critical level in the neighborhood of 5 grams per 100 cubic centimeters reduction in blood volume and dangerous tissue edema may occur. It must be remembered however that the albumin fraction is much more important than the globulin fraction in this respect, for although the albumin molecule comprises only about 60 per cent of the plasma protein it is a much smaller molecule than globulin and provides about 80 per cent of the colloid osmotic pressure of the plasma. It has been shown that the antibody properties of the plasma reside in the globulin component and reduction in this fraction by malnutrition prolonged abnormal loss or impairment of the body's power to form globulin lowers resistance to infection (2). The clotting power of the blood depends particularly on two components of the plasma protein namely, fibrin

USE OF BLOOD AND BLOOD SUBSTITUTES

JOHN D STEWART A B M D Buffalo New York

IN recent years much new information regarding the nature origin and function of different elements of the blood has become available through the researches of biochemists, physicists physiologists and clinicians. In many instances the clinical applicability of such information has been obvious and the patient has derived immediate benefit. In this field as elsewhere in medicine progress in the care of the sick depends not only on the fundamental contributions from laboratories of basic science but on the clinician's alert and intelligent appraisal of new facts and on his skilful application of these new facts in the clinic.

Whipple and his collaborators have done much to define the facts of protein metabolism and the conditions governing the regeneration of the plasma proteins and hemoglobin (10 14 15). The quality and quantity of protein ingested the state of the liver the presence or absence of infection or intoxications the factor of individual organismal variation and the availability of iron to the body have been shown to be critical conditions in the maintenance of normal hemoglobin and plasma protein concentrations and blood volume. They have shown that the healthy animal for example can replace all its circulating plasma protein in 3 days under the stimulus of plasma withdrawal while taking a protein rich diet. Hemoglobin which contributes six times as much protein to the blood as does plasma protein takes about six times as long for replacement. Body protein accretion (both new hemoglobin and tissue protein) is believed to go through the transition stage of plasma protein. The protein of the plasma thus constitutes a pool which is drawn upon by the cells throughout the body and which is in constant interchange with cell protein. The studies of

Schoenheimer and others using tagged elements supports the conception of continual and rapid movement of amino acids through out the proteins of the body. The blood then must be regarded as a tissue which is in dynamic equilibrium with the other tissues of the body and its composition and volume are maintained relatively constant only through a set of remarkably complex and continuous reactions.

Of particular interest to surgeons also is the work of Cohn and his group in the fractionation and characterization of the plasma proteins (3 4, 9). As methods have been developed for the separation of the different proteins of the plasma it has become possible to prepare them for tests of their function with a consequent better understanding of the physiological rôle of the individual proteins. The properties of the different fractions are of great clinical import and must be considered in the intelligent use of blood and blood substitutes. For example the colloid osmotic force of plasma proteins is essential to the maintenance of the volume of the circulating blood and when the plasma protein concentration falls below a so-called critical level in the neighborhood of 5 grams per 100 cubic centimeters reduction in blood volume and dangerous tissue edema may occur. It must be remembered, however that the albumin fraction is much more important than the globulin fraction in this respect, for although the albumin molecule comprises only about 60 per cent of the plasma protein it is a much smaller molecule than globulin and provides about 80 per cent of the colloid osmotic pressure of the plasma. It has been shown that the antibody properties of the plasma reside in the globulin component and reduction in this fraction by malnutrition prolonged abnormal loss or impairment of the body's power to form globulin lowers resistance to infection (2). The clotting power of the blood depends particularly on two components of the plasma protein, namely fibrin

ogen and the globulin prothrombin. In addition, an antihemophilic globulin has been isolated and this element, missing in hemophilia, can be supplied from normal plasma to control the bleeding of hemophilia. Largely through the work of Cohn and his group under the stimulus of war time needs, these various derivatives of the plasma proteins have been put to practical test for the benefit of the sick and the wounded.

These remarks serve as a reminder that in the use of blood and blood substitutes in surgical practice one is dealing with fundamental physiological considerations. The better the understanding of the need of the patient, the clearer the objectives and the less empirical the practice, the better the result.

The rest of this discussion will be concerned with two common surgical problems, namely hemorrhage and secondary shock. These conditions will be considered in relation to therapy by the intravenous administration of whole blood plasma, albumin solution and protein hydrolysates. By the latter term is meant the mixture of polypeptides and amino acids formed by the enzymatic breakdown of a high quality protein such as casein or lactalbumin. Such hydrolysates in 5 or 10 per cent solution are nonallergenic and nonpyrogenic when properly prepared. They may be regarded as a blood substitute in that they provide the essential amino acids for the construction of plasma protein and hemoglobin when given intravenously.

Hemorrhage. In the healthy adult the volume of the blood comprises about 8 per cent of body weight, but variations of from 6 to 10 per cent have been found in different individuals (8-18). The blood volume tends to remain constant in the same individual and is probably more closely related to surface area and height than to weight. The healthy person can withstand a sudden loss of one third the blood or even more (up to 1.5 or 2 liters) but this is not true of many of the patients the surgeon must treat. Malnutrition, previous hemorrhage, infection, trauma, disease of cardiovascular system, liver or kidneys, reduce the power of the organism to make the life-saving adjustments required in overcoming critical blood loss.

As previously noted the blood volume is not to be regarded as a fixed entity as if contained in a rigid walled vessel. Not only may the size of the vascular bed vary rapidly through vasodilatation or vasoconstriction and ischemic shunts, but the blood is in diffusion equilibrium with the larger reservoirs of interstitial and intracellular fluid. With loss of blood an immediate inflow of fluid from outside the capillary bed begins, a process which is detectable by fall in red cell count and hematocrit. Furthermore in hemorrhage protein is mobilized from parenchymatous organs such as the liver and red cells are drawn into circulation from the spleen and bone marrow. The more rapid the loss of blood, the less the time for successful compensation and the lower the physiological reserve of the patient the smaller his capacity to endure hemorrhage. It has been shown by studies of hemorrhagic shock in animals that the longer hemorrhagic hypotension and tissue anoxia are allowed to go uncorrected the less the likelihood of survival. After a certain point damage to such organs as the liver and brain becomes progressive. The urgent need for correction of blood loss is thus emphasized. Ideally the loss of blood should be made good as it takes place.

A great service has been done practicing surgeons by Coller and his co-workers, as well as others, in providing evidence that the amount of blood lost during common operations in good hands may be large (1.5-6.7-12-20). Many surgeons unquestionably had failed to appreciate that operative and post-operative shock commonly stemmed from uncorrected hemorrhage. Further proof is convincingly available in the major teaching clinics of the country today where by the free use of blood transfusion during and after operation surgical procedures of hitherto impossible magnitude are being successfully performed (13). As Coller has pointed out, (a) the amount of bleeding at operation is almost always greater than the surgeon suspects, (b) there is no practicable method of measuring the extent to which bleeding has occurred at any given time during operation and (c) replacement is most effective when whole blood is given as the loss occurs (5). Every

STEWART USE OF BLOOD AND BLOOD SUBSTITUTES

surgeon undertaking major surgical procedure should familiarize himself with the range of values for blood loss at various operations and ideally he should measure the losses at his own hands in a series of cases.

The replacement therapy for massive hemorrhage seems obvious though from time to time the obvious has been held suspect. Whole blood has been lost in the operative field into body cavities into tissue planes or to the surface and whole blood should be given in treatment (11-19). The blood must be carefully matched it must be given in large enough quantity it must be given without delay. The acutely depleted blood volume lowered cardiac output and tissue anoxia urgently require relief. In acute hemorrhage plasma or albumin injected intravenously will increase blood volume but further dilution of hemoglobin and crippling of the mechanism for oxygen-carriage results. Under these circumstances the systolic blood pressure may temporarily rise and produce a false sense of security while the patient's condition is actually worse.

Following a severe nonfatal hemorrhage unless the loss has been completely corrected by blood transfusion a period ensues during which anemia, hypoproteinemia and reduced blood volume are common findings. Unless the patient is receiving large amounts of iron the anemia is apt to be of the hypochromic microcytic type and the hypoproteinemia may be associated with a relatively greater reduction of albumin than of globulin. During the convalescence from severe hemorrhage further blood transfusions may be indicated in order but protein requirements may be advantageously contributed to by infusions of plasma and albumin. A better source however of amino acids is protein hydrolysate in 5 or 10 per cent solution.

Secondary shock In the state of secondary shock as distinct from neurogenic transitory hypotension there are present reduction in cardiac output and blood flow fall in blood pressure and usually evidence of peripheral arteriolar constriction. As a rule there is lowered basal metabolic rate and body temperature rapid pulse shallow respiration and sweating. Secondary shock may be seen in

medical as well as surgical conditions and the syndrome may be classified on an etiological basis as follows:

- 1 Loss of propulsive force, or cardiogenic shock as seen in coronary occlusion and severe cardiac arrhythmias

- 2 Dilatation of the vascular bed as seen in overwhelming invasive infections or in transection of the spinal cord

- 3 Mechanical interference with blood flow as in volvulus of the intestine cardiac tamponade tension pneumothorax pulmonary embolism or mesenteric thrombosis

- 4 Primary reduction in blood volume as in wound shock hemorrhage, burns war gas poisoning and severe dehydration

The classification of secondary shock in this manner is of value in that it emphasizes the varied nature of forces which may produce the same clinical picture though in many cases more than one of these major causes may be at work. It follows that treatment will vary likewise.

It is probably a fair assumption that reduction in cardiac output is present in secondary shock due to any of the above causes and that lowered blood volume is present in most instances. However, blood transfusion may be dangerous rather than beneficial in cardiogenic shock or pulmonary embolism and though blood transfusion is helpful in intestinal strangulation it is equally important to correct the mechanical defect by early surgical operation. In the state of secondary shock due to fulminating infections restoration of blood volume by infusions of plasma and by blood transfusions is in order but of greater urgency perhaps is treatment of the infection itself as by surgical operation antibiotics and sulfonamides depending on the case (17). The uncritical use of blood transfusion in secondary shock without analysis of its cause is therefore to be condemned.

In the state of secondary shock due to losses from the circulation or in other words in primary oligemic shock, successful treatment must be based on knowledge of the nature of the losses. In wound shock, including the shock incident to surgical operation oligemia is due to loss of whole blood and the treatment that is needed is blood transfusion in su-

ficient volume. Furthermore the treatment of such cases of hemorrhagic oligemia does not end with recovery from the hypotension as was pointed out above. Incomplete restoration of lost blood, the presence of complicating infection, the wasting effect of the reaction of injury, raise the need for protein. The intravenous route must often be employed in meeting this need, and 5 or 10 per cent amino acids solutions, plasma, albumin and whole blood must be given.

To illustrate the need for discrimination further, the parenteral fluid requirements in wound shock and in burn shock may be compared. In both conditions there is severe reduction in the volume of circulating blood. In wound shock, however, whole blood has been lost, and the hematocrit and red cell count are normal or low, the plasma protein concentration is normal or low. In burn shock, plasma has been lost in large amounts and albumin frequently to a greater extent than globulin; the hematocrit and red cell count are sharply elevated. Correction of blood composition here is important as well as restoration of blood volume, and the immediate intravenous therapy of choice is infusion of plasma or albumin solution. In both wound shock and burn shock blood and protein hydrolysates and to a less extent plasma and albumin solution may be required intravenously in later convalescence.

CONCLUSIONS

In conclusion certain general principles involved in the use of blood and blood substitutes in the treatment of hemorrhage and shock are listed.

1. Careful matching of blood before transfusion is essential in minimizing reactions and renal damage; plasma for infusion should be of the pooled mixed variety or it should be typed.

2. Deficiency of hemoglobin and deficiency of plasma protein often occur together whether the lack is acute or chronic.

3. In the restoration of depleted blood volume by intravenous injections normal blood

composition as well as normal volume should be the aim.

4. Acute losses of hemoglobin are less easily repaired by the body than are losses of plasma protein.

5. In infections, toxic states and trauma regeneration of hemoglobin and plasma protein may be greatly impaired.

6. The longer tissue anoxia due to hemorrhage and shock is allowed to go uncorrected the less the likelihood that the patient will recover.

7. In hemorrhage and shock as seen in surgical patients the need for blood transfusion and for infusions of protein and the protein derivatives often continues during convalescence.

LIGATION OF THE INFERIOR VENA CAVA IN THROMBOSIS OF THE DEEP VEINS OF THE LOWER EXTREMITIES

J ROSS YEAL, M.D. F.A.C.S. HUGH HUDSON HUSSEY, M.D., F.A.C.P. and
EARL BARNES, M.D. Washington District of Columbia

LIGATION of the major veins to limit propagation of blood clots and prevent pulmonary embolism has become a standard procedure. The point of ligation of the involved vein depends upon the level of the blood clot and the extent of disease of the vein. The only safe rule to follow is to ligate above the clot through a normal segment of vein just below a main tributary. The majority of cases of thrombosis of the veins of the lower extremity can be detected while the clot is still below the inguinal ligament. In these, ligation of the femoral vein for the deep venous thrombosis, and the saphenous vein for superficial thrombosis usually terminates the process. However in some cases the disease has extended to such a level that ligation of the inferior vena cava becomes necessary. Ligation of the inferior vena cava is not a new procedure. It has been quite widely used in pelvic thrombophlebitis. However it has only recently been used to any extent in the treatment of thrombosis of the deep veins of the lower extremities. We have performed ligation of the inferior vena cava in 30 cases of ascending thrombosis of the deep veins of the lower extremities. A report of these cases forms the basis for this communication.

INDICATIONS FOR LIGATION OF INFERIOR VENA CAVA

Although the indications for ligation of the inferior vena cava were essentially the same in all of our cases, the basic venous pathology was quite varied (Chart 1). In this series there were 3 types of venous thrombosis, namely phlebotrombosis, acute femorotibial thrombophlebitis, and thrombophlebitis in varicose

veins (Table I). The relative dangers of pulmonary embolism in the various types and the necessity for ligation of the inferior vena cava in the cases we are reporting can best be shown by description of the pathology and clinical course of each type.

PHLEBOTROMBOSIS

Phlebotrombosis usually begins in the small veins of the legs or feet. The clot is attached at first only at its origin. Propagation is the characteristic quality of this type of venous thrombosis. As the original mass of clot begins to organize the vein wall at this level becomes thickened, edematous, and inflamed. As new clot is added it extends steadily upward floating freely in the blood stream. The clot gradually fills the involved veins and eventually becomes organized and fixed to the vein wall. This process may require many weeks. Until there is complete organization and fixation of the thrombus it may be dislodged at any time and produce pulmonary embolism. Phlebotrombosis is particularly dangerous because at first there may be no local symptoms. Its existence often becomes known only after the patient has suffered one or more episodes of pulmonary embolism. As the clot extends upward more venous channels become occluded and local signs and symptoms develop. In all of the cases in this series there were local signs and symptoms of venous thrombosis. The common signs are edema of the foot, ankle, and leg; dilated superficial veins; cyanosis of the nail beds; and often a fall in local temperature. Pain in the calf is the most important symptom. This may be constant but is more often noted on motion of the foot or leg or on pressure over the veins. Fever is frequently absent and when present is quite mild. Leucocytosis is usually absent. Phlebotrombosis of the deep veins of the legs accounted for 25 of the cases in this series.

From the Departments of Surgery and Medicine of the Georgetown University School of Medicine.
Presented in the forum on Experimental Surgical Problems before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio December 6-9, 1946.

VEAL, ET AL. THROMBOSIS OF DEEP VEINS OF LOWER EXTREMITIES

pathetic blocks were performed over a 3 day period before there was relief of symptoms. The deep veins became thrombosed and superficial collaterals developed rapidly.

The remaining 4 unilateral cases all developed thrombosis of the deep veins of the normal side with massive edema of that limb. The process was gradual and at no time was there any disturbance of the arterial circulation. In all of our 30 cases there has been some degree of postoperative edema of both legs. This has been controlled by properly fitted elastic stockings. We have used a series of leg exercises in order to expand the collateral circulation gradually (Chart 3). The legs are elevated on 4 soft pillows immediately after operation. Walking motion exercises of the feet and legs are given frequently. As the edema subsides or if negligible throughout the pillows are gradually lowered. About 10 days following operation the patients are allowed to dangle legs over the side of the bed—still using the exercises. About 14 days after the operation the patients are allowed to walk. Elastic stockings are then fitted and are worn at all times except while in bed. The patient gradually resumes free activity. All of the patients that survived have been rehabilitated to the point of resuming full time occupations. There has been no ulceration of the legs. There is a marked difference in the rapidity of development of collaterals in the males and females. In the males the superficial collaterals have predominated in the females the deep collaterals, and often there is no dilatation of the superficial veins.

VENOUS COLLATERAL PATHWAYS FOLLOWING LIGATION OF THE INFERIOR VENA CAVA

When the inferior vena cava is ligated many collateral pathways develop. Some of these carry blood back to the inferior vena cava above the point of ligation. Others communicate with the portal vein or the superior vena cava. Among the most important deep collateral routes is the communication of the hypogastric vein with the inferior mesenteric vein through the hemorrhoidal plexus. Another major route is from the external iliac vein through the inferior epigastric vein to the superior mesenteric vein and thence to the

Chart 3 Postoperative measures to restore venous circulation

superior vena caval system. In women an additional important deep pathway is found in the ovarian veins which have access to blood from the hypogastric veins through the pelvic and uterine plexuses and deliver it to the inferior vena cava directly or via the renal vein. In men the homologous pathway through the spermatic veins is considerably less efficient, which probably explains the clinical observation that the superficial abdominal veins usually are more prominent in men than in women after ligation of the inferior vena cava. The main superficial collateral circulation is from the femoral vein through the superficial epigastric vein to reach the superior vena cava system by communication with the lateral thoracic vein. Other veins which contribute to the collateral circulation include the vertebral venous system (communication through pelvic plexuses), the lumbar veins (communication through the deep iliac circumflex vein and iliofemoral vein) and the superficial iliac circumflex and superficial internal circumflex branches of the femoral vein.

NUTRITIONAL PREPARATION FOR SUBSTANDARD RISK PATIENTS

RICHARD I. VARCO, M.D. Minneapolis, Minnesota

THE number of publications which have appeared during the war years and since attest to the current interest among investigators and clinicians, in nutritional problems. As a consequence of these efforts it is now possible to list better methods for solving the dilemma of the surgeon contemplating a major operation on a patient who is a substandard risk as a result of a chronic dietary deficiency. When from unhappy personal experiences, surgeons had learned to calculate the added risks these individuals suffered often in the past a number were denied benefits obtainable through surgery or if accepted after a genuine appraisal of the increased hazard the necessary surgical manipulations were found to be poorly tolerated. The patient seemed to react unfavorably from the outset with an instability of blood pressure out of proportion to the actual blood loss. Blood transfusions would often produce only a transient and unsatisfactory response. Frequently the convalescence was protracted complications developed to jeopardize the patient's life. In a considerable number a vitality sufficient to meet all the requirements for convalescence was so lacking that death occurred despite recourse to a variety of therapeutic measures. The usual autopsy findings of some incipient heart failure and bronchopneumonia, a fatty liver or a failure of wound healing were hardly an exception but rather confirmed the impression of operation but rather confirmed the impression that malnourished individuals presented a substandard risk. Too frequently the issue will continue to be settled tragically if surgeons persist merely in restoring to normal the hydration, electrolyte status, and hemoglobin

content. The statement has facetiously been offered that some modern surgeons find it necessary to operate by the calendar while others can 'work by the clock.' However a measure of wisdom may well be with the former when dealing with chronically starved patients because an increased experience with the preoperative phase of dietary preparation indicates that the success of an operation may hinge on the effectiveness of such nutritional care and makes unnecessary the completion of a hasty dissection before the patient's condition deteriorates. Such a statement implies that the pathologic biochemical states resulting from starvation are reversible after an appropriate dietary regimen. In nearly all except pre-mortem instances this is possible. The rate at which the lost body protein can be replaced is much slower though than when balanced anew the body electrolytes or fluids. Sudden dramatic results which capture attention are not the rule. The processes of nutritional restitution frequently require days may even take weeks and therefore demand of the surgeon patience. In this regard there is a real need as yet unanswered for simple accurate methods of determining how seriously starved the patient actually is how much nourishment and how long, should he be fed before an operation can be undertaken without an added risk. Fortunately however a partial restoration of the bodily stores usually suffices to permit performance of the necessary operative procedure. That is to say all the fat need not be forced from the liver nor all depleted tissues refabricated nor the hypoproteinemia completely corrected or the immune globulins and phagocytic values restored to normalcy. Even though short of this goal, after a reasonable period of satisfactory preoperative food intake the surgeon can then anticipate a convalescence virtually as free of complications as that encountered among the standard risk group. A discussion of the meth-

From the Department of Surgery, University of Minnesota Medical School, Minneapolis.
The researches upon which this presentation is based were supported by a grant of the Graduate School of the University of Minnesota.
Presented in the symposium on Care of the Patient before and after Operation, before the Clinical Congress of the American College of Surgeons, December 16-20, 1946.

ods and nutrients employed upon the surgical service at the University of Minnesota Hospitals for realizing this represents the subject matter of this paper. It is hoped that the therapeutic outline offered will prove to have a broad practical application to the several nutritional problems faced by surgeons and by virtue of its relative inexpensiveness, simplicity of preparation and apparent effectiveness, merit trial in the preoperative dietary preparation of surgical patients.

FACTORS RELATED TO LIQUID DIETS FORTIFIED WITH PROTEIN AND CARBOHYDRATES

During semistarvation or starvation periods, man just as any experimental animal becomes autocannibalistic while deriving his energy from body fat and protein. This means that his diet necessarily is low in calories, carbohydrates, and protein but relatively high in fat. From this one might predict that a diet of opposite qualities, namely high in protein carbohydrates and caloric content, would be best suited to correcting those abnormalities ascribable to this starvation regimen. The results of numerous investigations and clinical experience have confirmed this impression.

Of these several constituents experience and experimentation have demonstrated that protein plays a chief rôle. The principal sources of protein in natural foods are meat, fish, eggs, certain dairy products and cereals. Yet, in each of these, the protein contributes but a fraction of the total bulk. It therefore becomes necessary to consume relatively enormous quantities of food when very high protein diets are desired. For example, to realize an intake of 300 grams of protein from beef a pot roast between 3 and 4 pounds would have to be eaten. This is a feat usually beyond the capacity of any individual weakened and apathetic from prolonged starvation and is an impossibility in the case of those patients with stenosis or obstruction due to a lesion at the pyloric outlet. Desirable as it may be to foster the consumption of a high protein diet by pleasant appearing tastily prepared menus, the physical factors indicated above limit the accomplishments possible by this means. In order to pyramid the intake from such means,

liquid dietary supplements fortified with a protein concentrate and ordinarily also a carbohydrate can be used. A variety of protein concentrates are at present available, and among these is skim milk powder with the following composition:

Components	Per cent
Protein	37.8
Casein	5
Lactalbumin	5.2
Lactoglobulin	5
Carbohydrate (lactose)	49.7
Fat	1
Water	3.0
Ash	3.5

An experience has been acquired with use of this fortifying substance in diets prepared for treating several hundred malnourished surgical patients on the surgical service of the University of Minnesota Hospitals. Skim milk powder has a low cost, is readily and widely available in quantity stores well in the bulk, and can be fairly well disguised in a variety of palatable mixtures. The proteins present are complete, possess a medium capacity to induce plasma protein regeneration under experimental conditions, and are rich in the liver protecting amino acid methionine. In addition much of our biologic information on nutrition has been acquired using those proteins present in skim milk powder. They have repeatedly proved excellent sources when fed in quantity.

The use of a liquid diet either as a supplement to the hospital fare or as the sole source of calories finds frequent and valuable application in the care of patients with surgical lesions of the esophagus, stomach, and duodenum. A tale of recent weight loss can usually be found written in their admission history. This is particularly true when mild or serious degrees of obstruction are an associated complication of the disease process. Here not uncommonly the oft repeated acceptance of an incompletely masticated bolus of solid food leads to an insoluble problem in aboral transport and results in an even greater degree of obstruction and retention. Yet, it has not been unusual to note that when the lumen has been freed of these chunks by repeated washings, very satisfactory volumes of a liquid diet are accepted daily with little or no retention.

VARCO NUTRITIONAL PREPARATION FOR RISK PATIENTS

The fluid character of these liquid mixtures has an appeal for the dietetic staff burdened by a number of requests for special trays. Untrained workers can be easily instructed to perform the simple compoundings involved in the preparation of these formulas. Too the use of liquid diets with a fixed caloric value has made relatively easy and practical the measurement calculation and charting of the daily caloric intake on the same sheet with temperature pulse and respiration. Nutrition is thus brought into focus at the bedside whenever chart rounds are being held. This method of day to day contact with the problem and an accounting of the progress made consistently satisfactory care of those classified as substandard risks have been tried but the following with some variations, has appeared most adaptable

Fig 1 Drip feeding apparatus.

tubing and flow rates are thus visualized and regulated by a thumb screw attachment

Most patients however are able to drink the mixture and as it is the taste is similar to that of an eggnog. It can of course be flavored to suit the individual desire with chocolate cocoa vanilla or other disguising substances. Some such variation is frequently employed by out patients undergoing dietary preparation. These patients can obtain skim milk powder by prescription from the bulk stock in the drug room. Simple mimeographed directions about preparation volume to be consumed daily, and the refrigeration requirements are given to them during the course of the out patient workup. A brief explanation to this group of the importance to them of this dietary preparation usually suffices to insure their co-operation. Preparation from the out patient approach is frequently possible except in the case of the very debilitated and hence reduces the actual period of hospitalization in many instances to about that for the more standard risk group. Whenever this liquid diet constitutes the sole source of food for the patient, he is urged to take if possible about 5000 calories, i.e. 3 liters daily. In the absence of obstruction this is no great problem and the consumption of quantities greater than this is not unusual. If the diet is used as a supplement, the acceptance of even a liter adds materially to the protein and caloric intake for that day. Diarrhea has been a problem sporadically. It usually can be avoided

Beet, cane sugar or cerelese can be substituted.

This mixture passes readily through an indwelling nasal tube. It can therefore be employed as a drip feeding mixture in an apparatus similar to that in Figure 1. This is employed when caring for persons so enfeebled by their disease and starvation that it is impossible for them to make the efforts necessary to get adequate amounts of food from bedside trays. For this setup it has proved advantageous to use an intravenous flask with a dependent air vent. This permits the entering bubbles as they rise to agitate gently the mixture and hence reduces the tendency to plugging through sedimentation. A Murphy drip apparatus is inserted into the connecting

through the maintenance of appropriate refrigeration of all portions of the diet rather than the patient's immediate requirements and by the routine use of thoroughly cleansed or sterilized dispensing equipment. Should it occur despite attention to these precautions, modest doses of paregoric and ambogel will ordinarily correct the situation. Patients with ulcerative colitis or regional enteritis are rather consistent exceptions to this, however, and may develop an aggravatingly persistent diarrhea. The use of this mixture therefore is best avoided or limited to small quantities while testing the patient's tolerance.

As indicated earlier, satisfactory objective measurements of the accomplishments of a refeeding regimen are virtually nonexistent. By trial and error methods, it has been possible to arrive at estimates of how long a patient should receive a calorie intake augmented to about 4000 or more calories daily. From experiences with several hundred nutritional problems, the conclusion has been reached that if 5 to 7 days are devoted to such dietary preparation for each 1 per cent of the body weight lost, the individual will consistently be able to tolerate extensive surgical procedures. These values are admittedly empirical and probably maximal rather than minimal. Until more critical tests are available, however, the present method offers a reasonably reliable means for calculating the duration of the special dietary regimen.

REASONS FOR DIETARY PREPARATION PREOPERATIVELY

It will be noted that emphasis has been placed upon preparation being preoperative. This appears to be an important consideration because the weight of evidence at this time indicates a greater retention of nitrogen ingested during this phase rather than after an operation. Data from a number of laboratories (2, 4, 7, 10) as well as ours (11) confirm the accelerated loss and difficulty of securing a favorable balance of nitrogen in the recovery phase after surgery. In addition, such difficulties are pyramided when the patient after an intestinal operation is unable to take nourishment for several days because of ileus, nausea or vomiting.

OTHER SOURCES OF PROTEIN AVAILABLE FOR SUPPLEMENTING DIETS

Besides skim milk powder, various substances are available as fortifying materials. The data of Madden and Whipple (6) suggest a number of possibilities. Two of these, homogenized raw pork liver and powdered bovine plasma protein, have been tested and each demonstrated (12, 13) to be definitely superior to skim milk powder for the production of protein. Unfortunately, the possibility of controlling brucellosis appears too real to permit routine use of the former. The latter so far has been obtainable only in quantities sufficient for investigational purposes despite the fact that countless tons are potentially available in the blood now sold as fertilizer or stock feed. Whereas, estimates of manufacturing costs are high when calculated on the amounts available from a few pilot plants, the application of modern production methods on a larger scale would likely result in price reductions sufficient to permit its less restricted usage. The incentive to develop the manufacturing of this product by the packing industry necessarily will await a more generalized medical recognition of and demand for just such a superior dietary protein. In a similar fashion, a large portion of the protein of fresh caught tuna, mackerel and sardines is lost to human consumption (3). This, under current commercial practices, inedible fraction can be separated from its unpalatable characteristics and in this purified form possesses high biological value for hemoglobin and plasma protein formation. These tests, limited to date to small animals, might profitably be extended to clinical material. Yeast has received somewhat limited attention as a source of protein for humans due to its rather low content of sulphur, containing amino acids and because of an objectionable odor and taste which are quite difficult to disguise. These several drawbacks have been virtually eliminated in products recently developed from new strains (9). The result is a powder virtually free of unpleasant aromatic or gustatory characteristics, with as much as a 70 to 80 per cent protein content. Its effectiveness as a dietary supplement for man remains unmeasured. These to mention but a few con-

VARCO NUTRITIONAL PREPARATION FOR RISK PATIENTS

tributions of biochemists to general nutritional problems offer a partial solution of the search for more, better and cheaper proteins with high biological activity. Their trial in the management of clinical dietary problems assuredly seems warranted if the progress of our knowledge in this field is to parallel that in the laboratory. From the selection of materials now available for fortifying diets broad scope is offered to the investigator in developing dose combinations achieving the greatest effectiveness with the least cost and with the best palatability.

METHODS FOR PARENTERAL NUTRITIONAL PREPARATION

In certain nutritional problem cases, fortunately a rather small percentage the oral route is not available for protein and caloric repletion. On a surgical service this most often results from an obstructive lesion of the esophagus stomach or duodenum which will ultimately require a surgical procedure of considerable magnitude. In this situation the surgeon has essentially two alternatives. For one he can elect to make a jejunostomy for alimentation. His personal experience with this operation has been a limited but rather consistently unsatisfactory one. Despite the employment of a wide variety of mixtures, severe diarrhea has invariably appeared before the quantity of material being fed reached a desirable level. The attainment of a substantial nitrogen and caloric balance under these circumstances is of course unlikely. Even when this complication has been less troublesome convalescence has been less likely. This may be related to the well documented temporary inability to anabolize protein that exists after a traumatic episode and which has been carefully studied by several workers *vide supra*. The other alternative is the establishment of a parenteral feeding program for the dual purpose of meeting the patient's current caloric needs, and securing the maximal nitrogen retention possible under the circumstances. To this end a daily carbohydrate intake of 200 to 250 grams is realized through the use of 10 to 20 per cent glucose solutions intravenously and isotonic glucose solutions subcutaneously. Unless this much sugar is available to the body for energy re-

quirements quantities either of the body proteins or of infused nitrogenous compounds continue to be catabolized for fuel. The magnitude of the carbohydrate intake therefore bears an indirect but quite essential relation to the state of the nitrogen balance. Direct control of the state of the nitrogen balance however is regulated by the kind and amount of nitrogenous compounds injected. A portion of these requirements can be provided by protein hydrolysates or pure amino acid mixtures (5). The latter has not been available so far in this clinic. Several definite limitations exist with the use of the former. Between 15 and 20 hours are required to complete the infusion of six thousand cubic centimeters of 5 per cent each of the protein hydrolysate amigen and of glucose. This is about the maximum quantity acceptable in each 24 hours. If this casein hydrolysate is injected at rates much faster than this or in greater concentrations, unpleasant systemic manifestations in our experience become more frequent. The nitrogen content of this considerable volume of fluid is theoretically equivalent to 225 grams of protein. In some cases with a long history of extreme privation and continuing rapid loss of protein (burns, massive ulceration, etc.) this quantity of nitrogen would scarcely suffice if the entire amount were available for useful metabolic activity. Actually however in several experiments it has been demonstrated that the total nitrogen content of a 24 hour urine collection after a venoclysis of this type contains considerably more waste nitrogen than that obtained while feeding equivalent amounts of skim milk powder or powdered bovine plasma protein.

There are at least two reasonable explanations for these findings. Since differences in biological activity have been demonstrated for proteins from various sources to casein (i.e. superior in all around qualities to casein (i.e. bovine plasma protein) might provide a more utilizable hydrolysate if it were tried as the substrate. Or the hydrolysis by other than intestinal mechanisms, of these substances might lead to a decrease in the acceptability of the end products, perhaps through an incompleteness of processing. The salt content of amigen is of little consequence when only small

From the selection of materials now available for fortifying diets broad scope is offered to the investigator in developing those combinations achieving the greatest effectiveness, with the least cost and with the best palatability.

METHODS FOR PARENTERAL NUTRITIONAL PREPARATION

In certain nutritional problem cases forunately a rather small percentage the oral route is not available for protein and caloric repletion. On a surgical service this most often results from an obstructive lesion of the esophagus stomach or duodenum which will ultimately require a surgical procedure of magnitude. In this situation the surgeon has essentially two alternatives. For one he can elect to make a jejunostomy for alimentation. My personal experience with this operation has been a limited but rather consistently unsatisfactory one. Despite the employment of a wide variety of mixtures severe diarrhea has invariably appeared before the quantity of material being fed reached a desirable level. The attainment of a substantial nitrogen and caloric balance under these circumstances is of course unlikely. Even when this complication has been less troublesome convalescence has lagged. This may be related to the well documented temporary inability to anabolize protein that exists after a traumatic episode and which has been carefully studied by several workers *vide supra*. The other alternative is the establishment of a parenteral feeding program for the dual purpose of meeting the patient's current caloric needs and securing the maximal nitrogen retention possible under the circumstances. To this end a daily carbohydrate intake of 200 to 250 grams is realized through the use of 10 to 20 per cent glucose solutions intravenously and isotonic glucose solutions subcutaneously. Unless this much sugar is available to the body for energy requirements, quantities either of the body proteins or of infused nitrogenous compounds continue to be catabolized for fuel. The magnitude of the carbohydrate intake therefore bears an indirect but quite essential relationship to the state of the nitrogen balance. Direct control of the state of the nitrogen balance however is regulated by the kind and amount of nitrogenous compounds injected. A portion of these requirements can be provided by protein hydrolysates or pure amino acid mixtures (5). The latter has not been available so far in this clinic. Several definite limitations exist with the use of the former. Between 15 and 20 hours are required to complete the infusion of six thousand cubic centimeters of 5 per cent each of the protein hydrolysate amigen and of glucose. This is about the maximum quantity acceptable in each 24 hours. If this casein hydrolysate is injected at rates much faster than this or in greater concentrations, unpleasant systemic manifestations in our experience become more frequent. The nitrogen content of this considerable volume of fluid is theoretically equivalent to 225 grams of protein. In some cases with a long history of extreme privation and continuing rapid loss of protein (burns, massive ulceration etc.) this quantity of nitrogen would scarcely suffice if the entire amount were available for useful metabolic activity. Actually however in several experiments it has been demonstrated that the total nitrogen content of a 24 hour urine collection after a venoclysis of this type contains considerably more waste nitrogen than that obtained while feeding equivalent amounts of skim milk powder or powdered bovine plasma protein. There are at least two reasonable explanations for these findings. Since differences in biological activity have been demonstrated for proteins from various sources, a material superior in all around qualities to casein (i.e. bovine plasma protein) might provide a more utilizable hydrolysate, if it were tried as the substrate. Or the hydrolysis by other than intestinal mechanisms of these substances might lead to a decrease in the acceptability of the end products, perhaps through an incompleteness of processing. The salt content of amigen is of little consequence when only small

volumes are being employed but attains real significance (9 grams in 6000 cubic centimeters of 5 per cent solution) when large volumes are in use. This item becomes even more important in the presence of the hypoalbuminemia frequently present in just this type of patient. States of overhydration due to such liberal administrations of salt and serious enough to require temporary cessation of this therapy have been noted.

This listing of these limitations should not be construed to mean that the intravenous administration of protein hydrolysates is fruitless for no one can seriously contend but that it has an important rôle in nitrogen replacement therapy. Rather it is hoped that the recapitulation of such inherent defects will bring their existence to the attention of those who have not so far appreciated them. Fortunately the number of cases wholly dependent on parenteral feeding is in a minority. Such patients must be blessed with the services of conscientious house officer or interne because they demand of him and themselves an abundant patience and tact during the tedious hours of prolonged intravenous therapy. Without actually achieving the goal of large scale plasma protein regeneration those benefits which result from the employment of hydrolysates are certainly real and definitely worthwhile. Through their agency it is possible to halt or retard the steady protein losses from starvation and allied depleting mechanisms (ulceration, infection, hemorrhage). The nitrogen intake can also be augmented considerably by daily transfusions of plasma or whole blood. Although the total amount of nitrogen in a plasma or whole blood transfusion would be relatively small considered as dietary or hydrolysate nitrogen it is proportionately more valuable because a significantly smaller fraction is lost in the urine the 24 hours after administration. This situation is particularly true when comparison is made with hydrolysate nitrogen. In this connection it appears only fair when calculating the cost of such replacement therapy to base one's ultimate conclusions on the amount of nitrogen the body actually retains and has available for functional purposes, rather than considering solely the price of each intravenous flask

and its contents. The use of whole blood and plasma, particularly when the latter is from a pooled source, is assuredly not an unmixed blessing. The possibility of inoculating the recipient with the virus of infectious hepatitis has been emphasized recently (1, 8) and attention called to this serious hazard.

A nitrogen balance study by my associate, Dr. Arnold Kremen, and myself yields data illustrating some of the problems and limitations of parenteral alimentation discussed earlier. The final 5 day period of this study is probably a significant example of the body's greater inclination to accept and retain nitrogen when supplied orally rather than intravenously. As has been indicated, the surgeon will find a knowledge of nutrition a means of improving his care of those patients suffering from a recent serious weight loss. Failure to recognize this obligation and meet the augmented nutritional requirements of this group will be followed by an increase in the morbidity and mortality statistics. To avoid these complications, liquid diets augmented with protein rich materials are recommended whenever the oral route is available. For those patients requiring parenteral feeding a specific program, albeit a less satisfactory one, is offered.

COMPLETE OCCLUSION OF THE ABDOMINAL AORTA

Report of Two Patients Diagnosed by Aortography

ALISON HOWE PRICE, M.D. and FREDERICK B. WAGNER, Jr. M.D.
Philadelphia, Pennsylvania

IN 2 patients with complete aortic block just below the origin of the renal arteries diagnoses were made during life by direct translumbar aortic injection of radiopaque medium. In 1 patient, the diagnosis was confirmed by 2 subsequent aortograms while the other was proven at necropsy. The technique used has been described (8, 10).

CASE REPORTS

Case 1. T. H., a white man aged 43 years was admitted to Jefferson Hospital on February 8, 1945 with the chief complaint of pain in both ankles. He had been well until October, 1944 at which time he began to experience progressively increasing weakness of both legs with easy fatigability and pain below the knees on effort.

On December 7, 1944 while eating supper he had a violent periumbilical pain so severe that he came doubled up and broke out in a cold sweat. The pain remained localized to the periumbilical area lasted for 1 hour and was followed by a dull ache which persisted for several days. He was admitted to another hospital. The gastric analysis was normal and a x-ray study of the upper gastrointestinal tract revealed a small deformity at pyloric end of stomach suggestive but not conclusive of a small ulcer.

While in the hospital 5 days after the first acute episode of pain he experienced a sudden attack of excruciating pain which first involved his right foot and thigh then spread upward to the lower abdomen and finally down the other leg. The attack which lasted about 30 minutes, was accompanied by numbness, paralysis and extreme pallor of both lower extremities. The severe pain then subsided to a dull ache, and localized in both ankles. Sensation and motor power returned promptly.

Following discharge from the hospital, the patient experienced an almost constant ache in both ankles. The pain usually prevented sleep and necessitated sitting on the edge of the bed with his feet resting on a chair. At the time of admission to Jefferson Hospital he could not take more than 20 steps without experiencing pain in the calves.

One feature of the occupational history of possible importance was his employment in a cold storage room from 1941 to 1943 during which time he was intermittently exposed to low temperatures.

The patient was thin, weighed 135 pounds and appeared 50 years old. The temperature pulse and respirations were normal. Blood pressure was unobtainable in the lower extremities but in the left arm was 170/120 and in the right arm 160/120. Eyegrounds showed diffuse arteriolar constriction with increased tortuosity several pinpoint hemorrhages and one large hemorrhage in the extreme periphery of the left eye ground. The remainder of the examination of the head as well as the neck and chest was essentially normal. The abdomen was normal except for the fact that aortic pulsation could not be palpated. Arterial pulsations including the femoral popliteal posterior tibial and dorsalis pedis were not palpable in either lower extremity. Both feet were cold, the left colder than right.

The erythrocyte count was 4,400,000 hemoglobin 87 per cent, leukocytes 7,400 with normal differential count and platelets 194,000. The blood sedimentation rate was normal. Results of repeated urine tests were negative. The blood Wassermann and Kahn reactions were negative. The blood sugar, urea nitrogen, uric acid and serum proteins were normal. The urea clearance test was 105 per cent. The prothrombin time was 100 per cent and tests of venous clotting time in both arms and both legs revealed hypercoagulability of the blood. Venous pressure in the upper extremities as well as circulatory time performed by the calcium gluconate method were normal. The electrocardiogram showed a prominent Q-wave in leads II and III, suggesting coronary artery disease posterior in type.

Röntgenograms of the chest, abdomen and spine were essentially normal. Soft tissue examination of the lower extremities failed to show any evidence of calcification in the blood vessels. Study of the upper gastrointestinal tract with barium revealed thickened mucosal folds and slight distortion of the duodenal bulb suggestive of an old healed duodenal ulcer and the barium enema was normal.

Circulatory function tests in the lower extremities all indicated markedly impaired function. Skin surface temperature studies failed to show an appreciable rise after paravertebral lumbar sympathetic nerve block. Pentotonecscopy revealed no evidence of an abdominal mass as a source of extrinsic aortic pressure. The left internal iliac artery and vein were

Fig. 1 First aortogram in Case 1 showing complete transverse block of abdominal aorta at level of middle of second lumbar vertebra.

clearly visualized but no arterial pulsation was noted. A neurosurgical consultant reported normal neurologic findings and advised that lumbar sympathectomy would be of questionable value.

Massive obstruction in the iliac arteries and the aorta itself was thought the most likely possibility but coarctation of the aorta was also considered. It was felt that aortography might definitely prove the diagnosis. Accordingly this procedure was first performed on February 24, 1945, with aortic puncture at the level of the upper border of the first lumbar vertebra. The arteriogram revealed a complete transverse block of the aorta at the level of the middle of the second lumbar vertebra immediately below the origin of both renal arteries (Fig. 1). The renal arteries and their tributaries were well visualized and appeared normal. In order to rule out any errors in technique repeat aortography was performed on April 30, 1945, puncture being made one vertebral level lower, at the upper border of the second lumbar vertebra. On this aortogram (Fig. 2) practically all of the radiopaque medium was visualized within the superior mesenteric artery and its branches, and no portion of the aorta itself was definitely delineated. Anastomosis of the middle colic branch of the superior mesenteric artery with the left colic branch of the inferior mesenteric was well demonstrated on this examination. Since the second

Fig. 2 Second aortogram in Case 1 2 months later showing opaque medium within superior mesenteric artery and its branches. Arrow indicates large anastomotic communication between middle colic artery of the superior mesenteric and left colic branch of inferior mesenteric artery.

aortogram merely confirmed the findings of the first one by inference rather than actual demonstration of the block, the study was performed for the third time on June 4, 1945. The needle was introduced at the level of the second lumbar vertebra just above the area of anticipated block. This aortogram (Fig. 3) left no doubt as to the existence of the block, which was sharply delineated at precisely the same level as on the first examination. The large anastomotic channel between the superior and inferior mesenteric arteries was again visualized as well as an extensive paravertebral anastomosis.

Treatment and subsequent course. Anticoagulation therapy with dicoumarol vasodilator drugs (papaverine and niacinamide sodium citrate and sodium tetrathionate intravenously; and meclochol by iontophoresis) and the oscillating bed were employed during his 6 1/2 months in the hospital. One month after admission the patient developed an ischemic ulcer on the lateral aspect of the right leg just above the external malleolus (Fig. 4a). Despite the use of penicillin systemically, various local applications including blood ointment and the measures already mentioned to improve the arterial circulation in his lower extremities, the ulcer remained refractory throughout his hospital stay. He

Fig 3. Third aortogram in Case 1, 3 months after first aortography showing sharp delineation of the block just below the origin of the renal arteries. An extensive para vertebral anastomosis is demonstrated.

Fig 4. Photograph (a, above) shows ischemic ulcer of leg in Case 1 with complete healing (b) 8 months later.

During the preceding 10 years the patient had experienced numbness, tingling and weakness of the lower extremities particularly after prolonged effort but never any pain. He was treated for pneumococcal pneumonia in February 1943 in another hospital. The family history was not significant. The patient was a middle-aged thin man weighing 118 pounds, lying comfortably in bed. Temperature pulse and respirations were normal. Blood pressure in the left arm was 250/130 right arm 210/130 left thigh 124/100 and right thigh 130/108. Ophthalmoscopic examination revealed diffuse hypertensive retinitis with arteriosclerosis grade 3. The remainder of the examination of the head as well as the neck and lung fields were essentially normal. The heart was regular in rate, force and rhythm slightly enlarged to the left and there were low grade systolic murmurs at all the valve areas. There was a palpable aortic impulse in the epigastrium over which a systolic murmur was audible but no pulsations could be detected below this area. The remainder of the abdominal examination was normal. Examination of the extremities revealed a full strong radial pulse but arterial pulsations, including femoral, in the lower extremities were almost imperceptible.

was discharged on August 22 1945. At this time he could walk about 50 steps before experiencing pain in the calves and he was also able to sleep most of the night without pain in the ankles. Three months after the patient left the hospital his leg ulcer healed (Fig 4b) after having been present for 8 months. Follow up examination was last performed on November 26 1946, a year and 3 months after discharge. At this time the patient stated he felt well could walk three city blocks without having to stop because of pain and could do light work. Blood pressure in the left arm was 210/150 in the right arm 200/150 but unobtainable in the lower extremities. Aortic pulsation could not be detected and arterial pulsations in the lower extremities were still not palpable.

CASE 2 J D a white man aged 52 years was admitted to Jefferson Hospital on February 19, 1945 with the chief complaint of frontal headaches. These headaches which first started in December 1942 occurred when the patient arose in the morning and became progressively worse during the day. They could be relieved by rest and salicylate medication. In January 1943 he was informed by a physician that he had albuminuria and a systolic blood pressure of 260. Despite treatment by doctor he had almost daily frontal headaches with occasional dizziness.

The blood count revealed the hemoglobin to be 98 per cent, erythrocytes 5 000 000 and leucocytes 9 800 with normal differential count. The blood sedimentation rate was not increased. The blood Wassermann and Kahn reactions were negative. Repeated urinalyses revealed moderate albuminuria. The highest urine specific gravity was 1.008. The urea clearance test was 64 per cent and the phenolsulfonephthalein dye test revealed 25 per cent

Fig. 5. Aortogram in Case showing complete block at precisely the same level as in Case . Arrow indicates huge anastomotic channel between middle colic and left colic arteries as in Figure .

renal excretion in one half hour. The blood urea nitrogen was 30 milligrams. The venous pressure in the arm was 15 millimeters and the circulation time 15 seconds. The electrocardiogram suggested coronary artery insufficiency anterior in type.

A roentgenogram of the chest revealed emphysematous lung fields and a cardiac silhouette within normal limits. There was no notching of the ribs as might be expected with aortic coarctation. X-rays of abdomen and intravenous urogram were normal.

In spite of complete bed rest, sedation and salt poor diet the patient showed no improvement. Even with sodium amyltal narcosis there was no appreciable decrease in hypertension. On March 7, 1945 the patient signed his own release. It was felt that the probable diagnosis was coarctation of the aorta.

The patient was readmitted on March 27, 1945 with the same complaints. The physical examination revealed no significant changes since the last admission. Blood pressure in the left arm was 156/130 right arm, 160/110 left thigh 130/90 and the right thigh 120/90. The blood count and urinalysis revealed essentially the same findings as before. The sedimentation rate was still normal. Another intravenous urogram revealed ptosis of the left kidney.

Because the clinical picture simulated coarctation of the aorta and because roentgenograms of the chest

failed to confirm this belief it was felt that aortography might reveal the exact nature of the lesion. Accordingly this was done on March 23, 1945 puncture being made at the lower border of the twelfth thoracic vertebra. The aortogram (Fig. 5) revealed a sharply defined, complete transverse block at the left of the middle of the second lumbar vertebra, just below the origin of the renal arteries. No dye was visualized in the iliac arteries or lower portion of the abdominal aorta. A large anastomotic communication between the middle colic branch of the superior mesenteric artery and left colic branch of inferior mesenteric was well delineated as in Case 1.

The day following aortography the patient was discharged as unimproved.

Following the second discharge the patient went back to his usual work as a waiter. Except for headaches and mild dyspnea on exertion he was able to work until January 28, 1946. At this time he experienced moderately severe substernal pain, radiating down the left arm, accompanied by dyspnea. These symptoms became severe on February 2, 1946 and on February 4 he was admitted to the hospital.

The patient was orthopneic, cyanotic, dehydrated, and poorly nourished. He was drowsy but oriented and co-operative. The temperature was 100° degrees F, pulse 120 and respirations, 36. The blood pressure was 60/110 in the right arm but unobtainable in lower extremities. There were moist rales at both bases but heart sounds were strong; no murmurs noted. There was moderate abdominal distention.

Blood count revealed a hemoglobin of 12.5 per cent, erythrocytes 5,400,000, leucocytes 14,000 with 90 per cent neutrophils, and 10 per cent lymphocytes. Urinalysis revealed occasional granular casts but was otherwise normal. The sedimentation rate was not increased. The blood nonprotein nitrogen was 75 milligrams and carbon dioxide combining power 30 volumes per cent. The electrocardiogram showed changes indicating an acute anterior coronary occlusion with involvement of a large posterior branch. The patient became progressively more dyspneic and died 33 hours later. During this final admission he voided only 200 cubic centimeters of urine.

Postmortem examination was performed by Dr. Peter A. Herbut. The salient gross pathologic findings were generalized arteriosclerosis, bilateral pleural adhesions, pulmonary congestion and edema, terminal pneumonia, cardiac hypertrophy, atherosclerotic thrombosis of the abdominal aorta both old and recent, and bilateral polar renal vessels. The heart, aorta, and kidneys were of the greatest interest and the findings in these are given in some detail.

The heart weighed 555 grams. The pericardial and endocardial surfaces were smooth and glistening. The myocardium was firm, hypertrophied and reddish brown. There was no definite evidence of old or recent infarction. The valves were normal in number, size, shape, and position. Coronary ostia patent, and vessels showed moderate atherosclerosis.

The thoracic aorta showed moderate atherosclerosis with several plaques. The abdominal aorta

showed a complete thrombotic occlusion extending from the renal vessels to the common iliac vessels (Fig 6). The proximal 5 centimeters of the thrombus extending equidistant above and below the upper renal vessels, was recent, dark red friable, and only moderately adherent to the wall of the aorta in places. The portion extending from the lower renal vessels to the common iliacs including the proximal 4 centimeters of the right common iliac was dense grayish white, fibrous, firmly adherent and continuous with the wall of the aorta.

The kidneys weighed 130 grams each and measured approximately 12 by 7 by 5 centimeters. The capsules stripped with ease. The external and cut surfaces were deep reddish brown and the demarcations were sharp. There were 2 renal vessels to each kidney (Fig 6). The upper renal vessels were 4 to 5 centimeters in length 7 to 8 millimeters in diameter and patent. The lower renal vessels were 4 to 5 centimeters in length 2 to 3 millimeters in diameter and occluded. The pelvis and ureters were normal.

The salient histologic findings were pleural fibrosis, pulmonary congestion and edema, terminal pneumonia, myocardial fibrosis, atherosclerosis and thrombosis of the abdominal aorta, and benign nephrosclerosis.

Histologic sections of the lower portion of each kidney disclosed only slight ischemic atrophy. Sections through the upper portion showed severe congestion severe arterial and arteriolar sclerosis hyalinization of the glomeruli proliferation of the glomerular epithelium and occasional necrosis of glomerular tufts. Sections of abdominal aorta at level of injection for aortography showed no changes that could be attributed to needle puncture.

DISCUSSION

Visualization of the level and degree of arterial obstruction as well as the amount of collateral circulation following thrombosis and embolism is possible by means of arteriography. Although employed for this purpose in selected instances in the peripheral arteries (9) arteriography for diagnosis of aortic lesions has been practically neglected. According to a review of the literature on thrombosis and embolism of the abdominal aorta by Greenfield in 1943 there were 161 cases on record and in none of these was aortography done to establish the diagnosis during life.

Blakemore (1) produced total occlusion of the aorta just distal to the renal arteries by wiring and electrothermic coagulation of a syphilitic aneurysm in this location. He then performed aortography by direct injection of 70 per cent diodrast solution into the lower thoracic aorta. The roentgenogram which un-

Fig 6 Postmortem specimen of aorta and kidneys in Case 2 showing old thrombus below renal arteries and recent thrombus above renal arteries. Note bilateral polar renal arteries. Death occurred 10 months following aortography.

fortunately was poor because of motion by the patient, nevertheless revealed radiopaque medium within both renal arteries one very large collateral artery going down the right side posteriorly opacification of wire within the aneurysm and lack of visualization of the aortic bifurcation as evidence of complete obstruction. Farnas (3, 4) by means of retrograde abdominal aortography has demonstrated partial and complete occlusion of the aortic cone. So far as we are aware these represent the only previous reports of aortography in thrombotic occlusion.

It is interesting that, although the level of the block was identical in our 2 patients and both had hypertension the symptomatology was different. In the first patient, the symptoms centered about the diminished supply of blood to the lower extremities while in the second the symptoms were principally related to the hypertension. In both symptoms were slow in onset suggestive of a gradually narrowing process, but in the first the acute pain evidently represented completion of occlusion. Collateral blood supply to the lower extremities in this condition is mainly by anastomosis.

Fig. 5. Aortogram in Case 1 showing complete block at precisely the same level as in Case 2. Arrow indicates huge anastomotic channel between middle colic and left colic arteries as in Figure 2.

renal excretion in one half hour. The blood urea nitrogen was 20 milligrams. The venous pressure in the arm was 5 millimeters and the circulation time 12 seconds. The electrocardiogram suggested coronary artery insufficiency anterior in type.

A roentgenogram of the chest revealed emphysematous lung fields and a cardiac silhouette within normal limits. There was no notching of the ribs as might be expected with aortic coarctation. X-rays of abdomen and intravenous urogram were normal.

In spite of complete bed rest, sedation and salt poor diet the patient showed no improvement. Even with sodium amylal narcosis there was no appreciable decrease in hypertension. On March 7, 1945 the patient signed his own release. It was felt that the probable diagnosis was coarctation of the aorta.

The patient was readmitted on March 22, 1945 with the same complaints. The physical examination revealed no significant changes since the last admission. Blood pressure in the left arm was 136/130, right arm 190/110, left thigh 130/90 and the right thigh 70/90. The blood count and urinalysis revealed essentially the same findings as before. The sedimentation rate was still normal. Another intravenous urogram revealed ptosis of the left kidney.

Because the clinical picture simulated coarctation of the aorta and because roentgenograms of the chest

failed to confirm this belief, aortography might reveal the cause. Accordingly this was done, the procedure being made at the lower thoracic vertebra. The aorta was sharply defined, complete block just below the origin of the renal artery was visualized in the iliac arteries of the abdominal aorta. A large anastomotic channel between the middle superior mesenteric artery and the inferior mesenteric was well delineated.

The day following aortography the patient was discharged as unimproved.

Following the second discharge the patient went back to his usual work as a waiter. He had no chest aches and mild dyspnea on exertion. He worked until January 18, 1946. At that time he experienced moderately severe substernal pain, radiating down the left arm, accompanied by numbness in the fingers of the left hand. These symptoms became severe on February 3, and on February 4, he was admitted to the hospital.

The patient was orthopneic, cyanotic, and poorly nourished. He was drowsy but and co-operative. The temperature was 100 F, pulse 120 and respirations, 36. The blood pressure was 160/110 in the right arm but unobtainable in the lower extremities. There were moist rales at the bases, but heart sounds were strong, no murmur noted. There was moderate abdominal distention.

Blood count revealed a hemoglobin of 12.5 per cent, erythrocytes 5,400,000, leukocytes 24,000 with 90 per cent neutrophils and 10 per cent lymphocytes. Urinalysis revealed occasional granular casts but was otherwise normal. The sedimentation rate was not increased. The blood nonprotein nitrogen was 75 milligrams and carbon dioxide combining power 20 volumes per cent. The electrocardiogram showed changes indicating an acute anterior coronary occlusion with involvement of a large posterior branch. The patient became progressively more dyspneic and died 33 hours later. During this final admission he voided only 200 cubic centimeters of urine.

Postmortem examination was performed by Dr. Peter A. Herbst. The salient gross pathologic findings were generalized arteriosclerosis, bilateral pleural adhesions, pulmonary congestion and edema, terminal pneumonia, cardiac hypertrophy, atherosclerotic thrombosis of the abdominal aorta both old and recent, and bilateral polar renal vessels. The heart, aorta, and kidneys were of the greatest interest and the findings in these are given in some detail.

The heart weighed 355 grams. The pericardial and endocardial surfaces were smooth and glistening. The myocardium was firm, hypertrophied and reddish brown. There was no definite evidence of old or recent infarction. The valves were normal in number, size, shape and position. Coronary ostia patent, and vessels showed moderate atherosclerosis.

The thoracic aorta showed moderate atherosclerosis with several plaques. The abdominal aorta

Fig. 1 Introduction of valvulotome into aorta after placing traction ligature around aorta and stay sutures in periaortic fat

by digital pressure over the opening while the traction ligature was held taut thus bringing the exposed portion of the aorta into the wound and immobilizing it. A specially constructed valvulotome was then manipulated gently into the aortic opening and made to impinge upon the posterior wall of the aorta (Fig. 1). In contact with the latter the instrument was passed proximally within the aorta, its sheath tamponading effectively the wound in the aortic wall until its further progress was arrested within a cusp of the aortic valve. The hooked blade next was forced out of the sheath perforating the cusp in its dependent portion then the valvulotome withdrawn thus dividing the free margin of leaflet (Fig. 2). In this maneuver the instrument was withdrawn as a whole without pulling the blade back into its sheath. Upon withdrawal of the valvulotome hemorrhage from the opening in the aorta immediately be-

Fig. 2 Schematic representation of longitudinal section of aorta showing perforation of valve leaflet. Withdrawal upward of barbed blade divides free margin of cusp.

a problem of considerable magnitude. Its control was attempted by two methods. At the beginning of the experimental studies, closure of the defect by interrupted fine silk sutures placed in the aortic wall was the method employed. This resulted in a high mortality due to failure of the sutures to hold with tearing of the wall thus increasing the size of the wound to such an extent that uncontrollable hemorrhage ensued (Table II). The second procedure was found to be more effective. It consisted of digital tamponade of the bleeding point until the previously placed stay sutures or pursestring suture in the periaortic fat could be tied over an absorbable gelatin sponge which was manipulated beneath the

Fig. 4. The conical sheath and barbed blade of the valvulotome

Fig. 5. Beginning introduction of blade into sheath

Fig. 6. The valvulotome completely assembled

The instrument used in producing the valvular defects consisted of two separate parts: the first being an exterior brass sheath of graduated conical shape (Fig. 4) the smaller diameter being at the distal end the larger at the proximal end. By this arrangement tamponading of the aortic opening occurred as the distal end of the instrument was introduced into the aorta. The second part of the instrument consisted of a long barbed blade attached to the end of a long handle (Fig. 4). The latter upon being introduced into the sheath in the manner of a trocar into a cannula (Fig. 5) fitted snugly within the sheath so as to prevent the escape of blood around it. The interior of the sheath contained a circumferential ridge near its distal extremity which arrested further progress of the handle so as to permit only the blade to project from the distal end. Introduction of the sheath into the aorta was accomplished in each instance with the blade pushed in the sheath so as not to damage the interior of the aorta during the downward progress of the instrument toward the valve leaflet. The blade was thrust out only after the sheath had become engaged within the cusp (Fig. 2).

RESULTS

Twenty two animals were subjected to operation. There were 14 survivals and 8 deaths, a mortality of 36 per cent (Table I). All deaths occurred either during the operation or immediately thereafter and were due in each instance to severe blood loss from the aortic wound. No attempt was made to replace blood

by transfusion a fact which undoubtedly influenced the outcome in some cases. Table II summarizes the comparative mortality according to techniques employed to control hemorrhage from the aortic opening. In the first 7 animals operated upon stay sutures of fine silk instead of in the wall of the aorta instead of in the periaortic fat. Five of these animals died of hemorrhage because the sutures failed to hold cutting through the aortic wall and producing large rents which grew larger as further efforts at direct closure by suturing were made. Fifteen animals were operated upon with only 3 deaths (Table II) using the combination of periaortic fat suture and gelatin sponge tamponade of the bleeding point. A pursestring suture in the fat was found to be superior to interrupted stay sutures. The 3 deaths in the group treated by the fat suture-gelatin sponge technique resulted from hemorrhage incident to one or both of two factors: slipping of the sponge from its proper location during closure of an overlying fat and accidental enlargement of the unmanageable extent of the valvulotome during introduction of the valvulotome.

operation. Valvular lesions were found in 12 animals (86%). In 2 animals, no evidence of a valvular defect was noted (Table III). In the latter it is likely that the valvulotome failed to become engaged in a leaflet passing instead into the ventricular chamber during systole. Perforation or laceration of a cusp occurred in 8 animals while in only 4 animals was complete division of the free margin of the leaflet produced (Table III).

DISCUSSION

Of the technical aspects of the procedure described two features deserve special comment: first the effect of simple division of an aortic valve leaflet upon the ultimate course of aortic stenosis in the human and second the gelatin sponge tamponade method of controlling hemorrhage from a wound of the aorta. Regarding the former only hypothetical considerations are permissible from this preliminary report. As noted by Cutler and Beck (9) the presence of marked thickening, rigidity and calcification in the aortic valve in cases of stenosis would indicate that valvulectomy rather than valvulotomy may be necessary to alter favorably the circulation in these cases. Furthermore an estimate of the effect of either procedure is difficult in the absence of a satisfactory method of producing aortic stenosis in the experimental animal. Further experimentation in this field is indicated.

Concerning the gelatin sponge method of tamponading hemorrhage from the aorta one might regard the technique employed as being relatively insecure. While it would appear that direct suture of the aortic wound is preferable a lower mortality resulted in those

animals treated by the gelatin sponge method. These findings are in keeping with the work of Jenkins (14, 15) and his associates whereby the successful use of absorbable gelatin sponge was demonstrated in controlling hemorrhage from wounds of the heart, aorta, and vena cava in experimental animals.

SUMMARY

With a view toward its possible application to the treatment of aortic stenosis in human subjects, a technique of aortic valvulotomy in dogs is described.

ARTERIOVENOUS FISTULA EXPERIMENTAL STUDY OF INFLUENCE OF SYMPATHETIC NERVOUS SYSTEM ON DEVELOPMENT OF COLLATERAL CIRCULATION

RALPH A DETERLING Jr M D HIRAM E ESSEX Ph D and
JOHN M WAUGH M D F A C S., Rochester Minnesota

UP to the time of John Hunter the ligation of a major vessel had been avoided because it was a fearful procedure in the treatment of aneurysm owing to the high incidence of infection gangrene and secondary hemorrhage. Not until the early part of the nineteenth century was the concept accepted that collateral vessels were able to take over the function of a major artery in supplying adequate nutrition to the tissues. The high incidence of recurrence of symptoms as well as the development of severe trophic disturbances and gangrene after simple ligation of the artery proximal to the arterial and arteriovenous aneurysm (Anel ligation) led Makins in 1914 to suggest the simultaneous ligation of the companion vein. Further experimental and clinical studies of arteriovenous fistula by Holman (19-21 23 24) Reid (40 43) Pemberton and others (36 37) have established quadruple ligation and excision of the vascular lesion as an adequate means of treatment. Since a relatively small proportion of cases have been suitable for treatment by the Matas restorative endoarteriorrhaphy or the Blakemore Lord type of vein graft, we must be ultimately concerned with the degree of collateral circulation between an abnormal communication and results from a major artery and vein. Reid (42) in 1925 stated that the arteriovenous fistula is the most powerful stimulus to the development of collateral circulation known and consequently urged that sufficient passage of time should be allowed to permit the development

of adequate collateral circulation. The factor of time has been similarly emphasized by Matas Holman and by Pemberton and Black (36) Ilkin and many others.

It should be pointed out however that an arteriovenous communication acts entirely differently from other types of vascular lesions, which usually cause more or less obstruction with a resulting rise in resistance to the flow of blood through the affected vessels. In an arteriovenous fistula, on the other hand the blood in the arterial system on arriving at the fistula, enters a region of markedly reduced resistance and flows directly into the vein where its distal movement is obstructed by valves, by the decreasing caliber of the vessels and by elevated venous pressure. The blood consequently returns immediately to the right side of the heart thus by passing the distal arterial and capillary beds. The shunting of the arterial blood when sufficiently great, obviously deprives the distal tissues of the involved part of adequate nutrition and stimulates compensatory responses. To quote Holman (22) "All avenues of approach to the fistula open up to appear as it were the thirst of the fistula." As stated in the preceding paragraph, one important factor in disrupting normal vascular physiologic processes in a part distal to an arteriovenous fistula is the rise of venous pressure. It is obvious that the arterial blood under a tension of more than 100 millimeters of mercury on entering the venous system via the fistula will cause an elevation of the venous pressure which by contrast normally may be measured as a few centimeters of water. The mechanical obstructions to distal venous flow of this arterial blood mentioned previously are effective in diverting the greater part of the flow proximally toward the heart. This increase of volume flow and pressure results in a

operation. Valvular lesions were found in 12 animals (86%). In 2 animals no evidence of a valvular defect was noted (Table III). In the latter it is likely that the valvulotome failed to become engaged in a leaflet passing instead into the ventricular chamber during systole. Perforation or laceration of a cusp occurred in 8 animals while in only 4 animals was complete division of the free margin of the leaflet produced (Table III).

DISCUSSION

Of the technical aspects of the procedure described two features deserve special comment first the effect of simple division of an aortic valve leaflet upon the ultimate course of aortic stenosis in the human and second the gelatin sponge tamponade method of controlling hemorrhage from a wound of the aorta. Regarding the former only hypothetical considerations are permissible from this preliminary report. As noted by Cutler and Beck (9) the presence of marked thickening, rigidity, and calcification in the aortic valve in cases of stenosis would indicate that valvectomy, rather than valvulotomy may be necessary to alter favorably the circulation in these cases. Furthermore an estimate of the effect of either procedure is difficult in the absence of a satisfactory method of producing aortic stenosis in the experimental animal. Further experimentation in this field is indicated.

Concerning the gelatin sponge method of tamponading hemorrhage from the aorta one might regard the technique employed as being relatively insecure. While it would appear that direct suture of the aortic wound is preferable a lower mortality resulted in those

animals treated by the gelatin sponge method. These findings are in keeping with the work of Jenkins (14, 15) and his associates whereby the successful use of absorbable gelatin sponge was demonstrated in controlling hemorrhage from wounds of the heart, aorta, and vena cava in experimental animals.

SUMMARY

With a view toward its possible application to the treatment of aortic stenosis in human subjects a technique of aortic valvulotomy in dogs is described.

ARTERIOVENOUS FISTULA EXPERIMENTAL STUDY OF INFLUENCE OF SYMPATHETIC NERVOUS SYSTEM ON DEVELOPMENT OF COLLATERAL CIRCULATION

RALPH A DETERLING Jr MD HIRAM E. ESSEX Ph D and
JOHN M WAUGH MD, F.A.C.S Rochester Minnesota

UP to the time of John Hunter the ligation of a major vessel had been avoided because it was a fearful procedure in the treatment of infection rism owing to the high incidence of gangrene, and secondary hemorrhage. Not until the early part of the nineteenth century was the concept accepted that collateral vessels were able to take over the function of a major artery in supplying adequate nutrition to the tissues. The high incidence of recurrence of symptoms, as well as the development of severe trophic disturbances and gangrene, after simple ligation of the artery proximal to the arterial and arteriovenous aneurysm (Anel ligation) led Makins in 1914 to suggest the simultaneous ligation of the companion vein. Further experimental and clinical studies of arteriovenous fistula by Holman (19-21 23 24) Reid (40 43) Pemberton and others (36 37) have established quadruple ligation and excision of the vascular lesion as an adequate means of treatment. Since a relatively small proportion of cases have been suitable for treatment by the Matas restorative endoaneu rismorrhaphy or the Blakemore-Lord type of vein graft, we must be ultimately concerned with the degree of collateral circulation that results from an abnormal communication between a major artery and vein. Reid (42) in 1925 stated that the arteriovenous fistula is the most powerful stimulus to the development of collateral circulation known, and consequently urged that sufficient passage of time should be allowed to permit the development

of adequate collateral circulation. The factor of time has been similarly emphasized by Matas Holman and by Pemberton and Black (36) Elkin and many others.

It should be pointed out, however that an arteriovenous communication acts entirely differently from other types of vascular lesions, which usually cause more or less obstruction with a resulting rise in resistance to the flow of blood through the affected vessels. In an arteriovenous fistula on the other hand the blood in the arterial system on arriving at the fistula enters a region of markedly reduced resistance and flows directly into the vein where its distal movement is obstructed by valves, by the decreasing caliber of the vessels and by elevated venous pressure. The blood consequently returns immediately to the right side of the heart thus by passing the distal arterial and capillary beds. The shunting of the arterial blood, when sufficiently great obviously deprives the distal tissues of the involved part of adequate nutrition and stimulates compensatory responses. To quote Holman (22) 'All avenues of approach to the fistula open up to appease, as it were the thirst of the fistula.'

As stated in the preceding paragraph, one important factor in disrupting normal vascular physiologic processes in a part distal to an arteriovenous fistula is the rise of venous pressure. It is obvious that the arterial blood, under a tension of more than 100 millimeters of mercury on entering the venous system via the fistula will cause an elevation of the venous pressure which by contrast normally may be measured as a few centimeters of water. The mechanical obstructions to distal venous flow of this arterial blood, mentioned previously, are effective in diverting the greater part of the flow proximally toward the heart. This increase of volume flow and pressure results in a

Abridgment of part of thesis submitted by Dr. Deterling to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M. S. in Surgery.

Presented in the form of a Fundamental Surgical Problem before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16 to 20, 1946.

compensatory dilatation which is demonstrable in the centripetal venous channels as well as the right side of the heart. Distally in the extremity this elevated venous pressure also hinders circulation from collateral vessels that otherwise would be much more effective.

The presence of a region of markedly elevated venous pressure at the fistula serves to act as a block to the venous outflow of the distal parts by virtue of the pressure differential as well as the effect of keeping the distal valves in the veins shut. Since the normal direction of the arterial systolic thrust is centrifugal there is maintained a constant piston like force on the distal venous tree so that eventually as a result of the distention of the vessels and the direct pressure on the cusps, the valves may become incompetent. The magnitude of this effect depends primarily on the duration, size and location of the fistula. Secondary to this interference with normal venous drainage is an increase of the intercellular fluid and lymph. The scarring about a traumatic fistula may block some of the major lymphatic channels and thus contribute to the formation of edema.

Hence in the presence of a fistula, the distal parts are frequently deprived more effectively of a normal circulation than following actual ligation of the major artery or arteriectomy. That the so-called collateral circulation is unable to provide an adequate blood supply to the tissues is evidenced by the frequent occurrence of trophic alterations in the distal parts. Trophic changes are seen as well in persons who have congenital arteriovenous fistulas even when the maximal time for development of collateral circulation has elapsed. While gangrene is relatively rare following closure of an arteriovenous fistula in the lower extremity there is a high incidence of vascular insufficiency particularly in the aged which is manifested by chronic edema, intermittent claudication, ease of fatigue, sensation of heaviness and paresthesias. This was noted by Bigger who saw in his postoperative cases definite evidence that circulation is inadequate for sustained muscular activity. This is an important matter and one which has not received the attention which is its due. Other authors have seen fit to question the value of this type

of vascular response. La Roque in 1921 expressed the opinion that there was "much reason for believing that the development of circulation is antagonized by arteriovenous fistula." Elkin (8) in 1943 similarly pointed out the possible inadequacy of this collateral circulation when he said that this great collateral circulation was for the most part useless since the blood returns to the heart without nourishing the distal parts. Recently Freeman has called further attention to the vascular deficiency which may follow the surgical repair of arteriovenous fistulas. In the March 8, 1947 issue of the *Journal of the American Medical Association* Hennigman, Rives and Davis reviewed the results of the various operative procedures employed in a series of 53 cases of arteriovenous fistula. Local vascular insufficiency did not develop in any of the 8 patients treated by a restorative procedure whereas a third or more of those patients having an obliterative procedure suffered subsequently from the symptoms of vascular deficiency.

The acceptance by so many surgeons of the concept that great collateral circulation develops with time generally has resulted in a delay of 3 to 6 months in the treatment of arteriovenous fistulas. Consequently we were stimulated to attempt to determine the actual effective arterial collateral circulation present in a limb which had had a fistula functioning for periods of time up to one year. Further more, because of the claim of some investigators that attempts to improve collateral circulation (after time enough has elapsed for it to have developed) are foolhardy if not actually contraindicated an investigation was made of the cutaneous temperature in the limb distal to a long standing arteriovenous fistula, both before and after lumbar sympathetic ganglionectomy.

I. DEMONSTRATION OF COLLATERAL CIRCULATION IN A LIMB IN WHICH THERE IS A CHRONIC ARTERIOVENOUS FISTULA

Method. In 19 adult dogs under ether anesthesia, lateral arteriovenous fistulas were made, in the femoral vessels, 1 to 2 centimeters below the profundus branch of the artery by the suture method (7). The communication between the artery and the vein ranged from 1.5

Fig. 3. 2, left, Two weeks after bilateral lumbar sympathectomy, showing the isolated arterial collateral circulation (made immediately after excision of a fistula of 7 1/4 months' duration). 6 Two weeks after unilateral lumbar sympathectomy performed on the side of the fistula (left). In this case the picture was taken immediately after excision of a fistula of 7 1/4 months' duration.

isolated arterial tree with the complete arterio-venous bed.

Group III Method.—The legs of the 4 remaining animals of series A were perfused in the usual manner and the fistula was dissected free. Carrel clamps were placed on the proximal and distal vessels to occlude the arterio-venous communication effectively. Injection was then carried out and roentgenograms of the isolated arterial circulation were made. Later the clamps were released and the injection of the harum mass was completed as in group I. Roentgenograms were again taken.

Results.—This set of experiments showed clearly the paucity of arterial collateral circulation compared with the total vascular bed in the region of the fistula (Fig. 2a and b) in the same animal. A differential study of this kind in a group of animals having comparable fistulas of varying duration makes possible an understanding of the rate of development of the vascular changes. It is evident that the arterial response appears very rapidly reaching its maximal development early while the augmentation of the venous system is gradual, occurring during a period of many weeks.

Series B Method.—The remaining 7 animals were also used in a study of the effect of lumbar sympathetic ganglionectomy on blood flow and cutaneous temperature. In 4 animals, bilateral lumbar ganglionectomy was performed and in 3 the ganglionectomy was restricted to the side of the fistula. In all the animals, the arteriovenous communication had been active for about 7 months before sympathectomy. In this series the fistula was excised 2 weeks after sympathectomy (a) to demonstrate further the isolated arterial system as an entity and (b) to show any effect on this system that sympathectomy might have had. Immediately after the quadruple ligation and excision of the fistula, the injection of the isolated arterial tree was carried out as described for group II.

Results.—Roentgenograms were made of the lower arterial vascular bed of the sympathectomized animals after perfusion and injection. In the group on which bilateral lumbar ganglionectomy had been performed 2 weeks previous to the excision of the fistula there was a minor degree of vasodilatation and tortuosity of the small arteries just distal to

Fig. 2. a, left, Isolated arterial collateral circulation after occlusion of the abnormal communication with Carrel clamps. b The same animal after removal of the clamps and completion of the injection with the fistula patent. This indicates that the predominant vascular response has been venous.

crease of venous pressure and blood flow. This 'Medusa's head' in the region of the fistula is what many authors have referred to when they described the collateral circulation of an arteriovenous fistula. This is also an example of what one sees in a clinical angiogram of this type of lesion for the patent communication allows the contrast medium to fill the entire network of vessels and permits identification of the fistula. It must be realized that a clear picture of the arterial circulation is necessary to evaluate collateral circulation. Any obliterative surgical procedure will close the communication between the artery and the vein, and consequently exclude the dilated venous vessels from the collateral vascular supply. To demonstrate the isolated arterial bed, the following procedure was used:

Group II. Method.—In 4 animals the perfusion with Ringer's solution was carried out as described. The fistula was then exposed by cautious dissection without sacrifice of any major collateral vessel. The proximal artery and vein were identified and ligated adjacent to the site of the fistula. The distal vessels were similarly ligated and the fistula was excised. In all instances the arteriovenous com-

munication had been patent up to the time of closure. Injection was then carried out to demonstrate the arterial system alone.

Results.—In this series, a representation of the venous response to the presence of a chronic arteriovenous fistula was eliminated completely by excision of the fistula. The injected vessels represented only the arterial channels in the limb. These in turn were the true collateral circulation or that part of the circulation which would function after surgical closure of the fistula (Fig. 2b). The marked contrast in the appearance of the vessels before and after closure of the arteriovenous fistula cannot be over emphasized. However it must be admitted that there was a marked difference in the appearance of the injected vascular beds of successive animals. In some of the animals, except for the region from which the fistula had been excised the arterial tree was approximately the same in the control limb as in that with the fistula. On the other hand, a number of animals that had fistulas of the same size and duration had a definite augmentation of arterial circulation just distal to the fistula. With such variation possible, it was therefore necessary to compare in the same animal the

the region of the aneurysm (Fig 3a). This was seen also in the series without sympathectomy and represents the degree of arterial response primarily as a result of time. As the denervation had been bilateral, there was no significant gross difference in the general vascular bed of both limbs beyond that resulting from the aneurysm alone. The differences of cutaneous temperature of the limbs found are reported farther on in this paper. They were accounted for on the basis of differences in the circulation supplying the limbs.

In the animals which had sympathectomy only on the side of the fistula, there was a slight increase in diameter of the vessels on the denervated side over that of the control side. In all these animals, the greatest apparent increase was in the region just distal to the excised fistula (fig 3b) since here there were superimposed the outlines of those many small arteries which had dilated as a result of the aneurysm. However further evidence that the vasodilatation following sympathectomy affected the entire vascular segment will be presented in the section of this report dealing with cutaneous temperature.

Comment. A comparison of roentgenograms taken on animals having arteriovenous fistulas of shorter duration than the fistulas of the dogs already considered indicates that the arterial response is rapid requiring only a few days to be significant. This is in agreement with studies on the development of collateral flow by other investigators which have shown most of the channels involved in collateral circulation to be present at the time of an obstruction of a major vessel. The venous component of the circulation resulting from an arteriovenous fistula, on the other hand develops more slowly and relentlessly over a period of weeks or months, and is without beneficial effect on the limb. Concurrent with the local dilatation of the venous bed there are increases of circulating blood volume and cardiac size. Experimentally we have found microscopic evidence that there are pulmonary renal, cardiac and hepatic changes which may or may not be reversible.

On inspection of the arterial collateral circulation developed during a period of more than six months, it is important to note that

the localized region of increased vasculature is actually *distal* to the arteriovenous fistula. It would appear therefore that the small arteries, visualized by injection methods, had been subjected to an excessive function, but in a manner different from the usual collateral channels which develop in response to an obstructive lesion. The tremendous return flow of blood from the fistula toward the heart indicates that the dilated channels in the arterial system have been draining blood into the site of the fistula with its low pressure by diversion of much of the blood which flows normally to the pelvic structures and limb via anastomotic channels of the deep circumflex iliac, internal and external iliac, pudendal, gluteal and lateral sacral vessels among others. One may consider as well the possibility that when reversed venous flow occurs, some of this blood finds itself back in arterial channels, and by retrograde flow again enters the site of the fistula. Consequently with the fistula patent, these channels do not serve to by pass the lesion and act as supplementary vessels as in obstructive vascular lesions. In the latter by contrast, the accessory vessels have their greatest function and are the most numerous in the actual region of obstruction. They arise from the immediately adjacent derivatives of the affected vessels, particularly from the proximal branches. Consequently it is difficult to escape the belief that the arterial collateral circulation in the presence of an arteriovenous fistula may contribute much less to the subsequent viability of the limb after obliterative operation than is ordinarily believed. The rise of cutaneous temperature of the toes observed (5.41) after closure of a more proximal fistula is but a qualitative and not a quantitative index of the increase of distal blood flow. Consequently this rise of cutaneous temperature gives no indication of the actual amount of collateral circulation. That this increase of blood flow may be inadequate is attested by the reports of gangrene and circulatory deficiency following the repair of a fistula.

One would expect the beneficial effects of lumbar sympathetic block on collateral circulation to involve the entire limb in contrast to the response of the vessels to time alone, in which latter case the dilatation would very

probably be localized in the region of the fistula. To test this concept, as well as to determine the degree of influence that the sympathetic nervous system has on a limb subjected to the physiologic changes attending arteriovenous fistula of long standing we made studies on cutaneous temperatures as an indirect index of digital arterial blood flow

STUDIES OF CUTANEOUS TEMPERATURES OF ANIMALS HAVING CHRONIC ARTERIOVENOUS FISTULAS BEFORE AND AFTER LUMBAR SYMPATHECTOMY

Experimental studies (6, 11, 45, 46) have proved that under certain conditions the cutaneous temperature of the paw of an animal may be taken as an indication of the distal arterial blood flow. Consequently alterations of significant magnitude following sympathetic denervation should similarly serve as an acceptable indirect index of blood flow.

Methods. Two recording devices were employed in the measurement of cutaneous temperatures: (1) the Tyco's dermatometer galvanometer apparatus with thermocouples adaptable to flat skin surfaces and (2) a mercury-bulb chemical thermometer used for measuring the temperature between the toes of the animal. Readings were taken in triplicate and careful control of the environmental conditions was exercised as advocated by Sheard (45) and Roth. A constant air temperature of 26 degrees C. was maintained and the humidity was kept at 40 per cent. Linear air movement was limited to 15 to 30 feet (4.6 to 9 meters) per minute. The skin surface was always dry clean and smooth shaven. The animals were kept comfortably recumbent for one hour to allow adjustment of the vasomotor system to a constant temperature. They were fasted 18 hours to exclude metabolic effects and the readings were taken at the same hour each morning to avoid diurnal variation.

These studies were performed on the same group of 19 animals used for the arteriographic studies already described. During the 8 to 10 month period of observation the increase of circulating blood volume (average increase of 31 per cent) and heart size (average increase of 32.5 per cent) was noted. Together with the signs of arteriovenous fistula—vibratory con-

tinuous thrill, machinery murmur, distended pulsating venous channels, bradycardiac reflex, and so forth—there was adequate evidence that the fistula was patent during the entire time.

Results. The average normal temperature gradient as determined by cutaneous thermocouple readings on the medial aspect of the hind leg of a normal animal, from Poupart's ligament to the toes, was recorded. These values are those obtained on the control or right hind limb of the animals having left femoral arteriovenous fistulas (Table I a). From a temperature of 37.0 degrees C. obtained at the groin of the normal limb there was a gradual decrease distally to 31.5 degrees C. as measured in the interdigital web of the foot. On the leg with the fistula the temperatures ranged from 37.5 degrees C. at the groin to 30.0 to 30.5 degrees C. at the toes. In this limb, however, the thigh was warmer than proximally in the groin because of the presence of the aneurysm (38.5° C.). This effect by virtue of increased vascularity in the region of the aneurysm has been utilized clinically to localize a fistula. The great distention of superficial vessels made this entire thigh warmer than on the control side but there was a rather sharp decrease of temperature of the ankle and foot to a value below that of the normal side.

the region of the aneurysm (Fig 3a) This was seen also in the series without sympathectomy and represents the degree of arterial response primarily as a result of time As the denervation had been bilateral, there was no significant gross difference in the general vascular bed of both limbs beyond that resulting from the aneurysm alone. The differences of cutaneous temperature of the limbs found are reported farther on in this paper. They were accounted for on the basis of differences in the circulation supplying the limbs.

In the animals which had sympathectomy only on the side of the fistula, there was a slight increase in diameter of the vessels on the denervated side over that of the control side. In all these animals, the greatest apparent increase was in the region just distal to the excised fistula (fig 3b) since here there were superimposed the outlines of those many small arteries which had dilated as a result of the aneurysm. However further evidence that the vasodilatation following sympathectomy affected the entire vascular segment will be presented in the section of this report dealing with cutaneous temperature.

Comment. A comparison of roentgenograms taken on animals having arteriovenous fistulas of shorter duration than the fistulas of the dogs already considered indicates that the arterial response is rapid requiring only a few days to be significant. This is in agreement with studies on the development of collateral flow by other investigators which have shown most of the channels involved in collateral circulation to be present at the time of an obstruction of a major vessel. The venous component of the circulation resulting from an arteriovenous fistula, on the other hand develops more slowly and relentlessly over a period of weeks or months, and is without beneficial effect on the limb. Concurrent with the local dilatation of the venous bed there are increases of circulating blood volume and cardiac size. Experimentally we have found microscopic evidence that there are pulmonary renal cardiac and hepatic changes which may or may not be reversible.

On inspection of the arterial collateral circulation developed during a period of more than six months, it is important to note that

the localized region of increased vascularization is actually *distal* to the arteriovenous fistula. It would appear therefore that the small arteries, visualized by injection methods, had been subjected to an *excessive* function, but in a manner different from the usual collateral channels which develop in response to an obstructive lesion. The tremendous return flow of blood from the fistula toward the heart indicates that the dilated channels in the arterial system have been draining blood into the site of the fistula with its low pressure by diversion of much of the blood which flows normally to the pelvic structures and limb via anastomotic channels of the deep circumflex iliac, internal and external iliac, pudendal, gluteal and lateral sacral vessels among others. One may consider as well the possibility that when reversed venous flow occurs, some of this blood finds itself back in arterial channels, and by retrograde flow again enters the site of the fistula. Consequently with the fistula patent, these channels do not serve to by-pass the lesion and act as supplementary vessels as in obstructive vascular lesions. In the latter by contrast, the accessory vessels have their greatest function and are the most numerous in the actual region of obstruction. They arise from the immediately adjacent derivatives of the affected vessels, particularly from the proximal branches. Consequently it is difficult to escape the belief that the arterial collateral circulation in the presence of an arteriovenous fistula may contribute much less to the subsequent viability of the limb after obliterative operation than is ordinarily believed. The rise of cutaneous temperature of the toes observed (5,41) after closure of a more proximal fistula is but a qualitative and not a quantitative index of the increase of distal blood flow. Consequently this rise of cutaneous temperature gives no indication of the actual amount of collateral circulation. That this increase of blood flow may be inadequate is attested by the reports of gangrene and circulatory deficiency following the repair of a fistula.

One would expect the beneficial effects of lumbar sympathetic block on collateral circulation to involve the entire limb in contrast to the response of the vessels to time alone, in which latter case the dilatation would very

DETERLING ET AL. ARTERIOVENOUS FISTULA

anesthesia or operation (Fig 5a'). This functional change in the response to stimuli which normally call forth a high degree of vasomotor activity had been similarly seen previously in the cool room experiment in which the normal limb did not constrict as well as the normal limb. This abnormal response may be explained by (1) altered distribution of blood volume in the limb, (2) the abnormal rôle of venous channels in carrying arterial blood and (3) disturbance of the functional and structural characteristics of the vessels as a result of long standing effects of the fistula.

A number of preliminary trials with ether anesthesia demonstrated this delayed response of the abnormal leg to be a constant finding. Despite the evidence of good collateral circulation we performed our operative removal of the lumbar sympathetic ganglia (L2 to and including L5) with the intervening chain by a transabdominal route. In 4 animals, the extirpation was bilateral in one stage so that there might be a control side with which to compare the physiologic response to sympathectomy. In the remaining 3 the procedure was carried out only on the side on which there was a fistula. This would more clearly reveal the results to be expected from clinical application of sympathectomy to a limb having an arteriovenous fistula.

Cutaneous temperatures of the toes and entire limb were obtained after the sympathectomy and these observations were recorded daily thereafter for more than two weeks. Then after a cool room test, the fistulas of 2 animals from both groups were excised after quadruple ligation.

Bilateral sympathectomy—Before sympathectomy the previously normal right leg showed a marked gradient of from 37.0 degrees to 31.5 degrees C. whereas after sympathectomy the skin surface of the entire limb was close to 37.0 degrees C. being lowest (35.5 C.) at the ankle (Table 1b). This demonstrated a maximal response of the cutaneous vessels to vasomotor denervation. The left limb which had had an arteriovenous fistula in the thigh for 7 months responded in much the same manner except for quantitative differences. As before sympathectomy, the thigh and leg were warmer than those of the

Fig 5. Cutaneous temperature of the toes of the normal foot and of the leg with the fistula, 7 months after its production. In addition to rectal and air temperatures a response to light ether anesthesia: a, deep ether anesthesia and concurrent left lumbar gangliectomy; b, cool room experiment; c, quadruple ligation and excision of the fistula.

control limb but the foot and toes were 0.5 to 1.5 degrees C. cooler than those of the control sympathectomized side. This relationship of toe temperatures therefore continued to be constant, even after sympathectomy indicating the rôle the fistula plays in preventing a normal distal blood flow, regardless of environment or vasomotor activity.

Following the bilateral sympathectomy the same elevation of cutaneous temperatures of the toes was recorded as was obtained when the animals were under deep ether anesthesia preliminary to both unilateral and bilateral sympathectomy (Fig 5a'). During the succeeding 2 weeks however the temperature of both limbs decreased gradually about 1.0 to 1.5 degrees C. as measured between the toes.

When these animals were given the cool room test, that is exposure to an air temperature of 18 degrees C. for 30 minutes, neither limb showed significant evidence of vasoconstrictive ability. In 2 of the animals that had bilateral sympathectomy of 2 weeks duration the fistula was isolated and removed by quadruple ligation and excision. It was immediately noted that the removal of this communication was attended by a slight but significant rise in toe temperature to almost the equal of that of the control side. This is explained by a redistribution of arterial blood through the distal artery.

Fig. 4. Cutaneous temperature of the toes, in addition to rectal and air temperatures—the operative production of left arteriovenous fistula, *b* cool room experiment *c* quadruple ligation and excision of the fistula.

Having demonstrated by arteriograms that these dilated channels did not extend to the foot we could depend with considerable confidence on temperature changes of the toes as being a reliable index of arterial flow.

In order to follow these changes closely, cutaneous temperatures of the toes were measured daily following the establishment of an arteriovenous communication in the left femoral vessels. Concurrent recordings were made of the rectal and air temperatures in order to note excessive variations of temperature in the body or in the environment. The control values noted prior to the vascular operation were rather constant (Fig. 4). Immediately after the production of an arteriovenous fistula there was a sharp drop of toe temperatures of the limb on which operation had been performed almost to room temperature (Fig. 4a). This was due to (1) vasospasm resulting from manipulation and (2) the distal ischemia due to the blood flow into the low pressure region at the fistula rather than to the tissues beyond. During the next day there was a sharp rise of the temperature of the leg with the fistula of about 2 degrees C., probably representing a decrease of vasospasm that had resulted from the operation. The normal leg and rectal temperatures rose slightly as evidence of a general reaction to the operation. This lasted but 1 to 3 days, and thereafter these temperatures followed the normal levels

(toe = 31.5° C. average rectal = 38.0° C. average). During subsequent days the toe temperature of the limb with the fistula increased but became relatively constant about 10 degree to 20 degrees C. below the control temperature of the right limb in 7 to 11 days.

In the subsequent period the response of the limbs to an abnormally cool environment was studied (Fig. 4b). On several occasions each animal was exposed to air temperature of 18 degrees C. for 30 minutes, and 15 minutes after removal of the animal to a room at about 26 degrees C. the temperature of the toes was recorded. It is significant that the normal side responded most efficiently to alterations of external environment. This greater vasoconstrictive ability of the normal limb made the leg with the fistula seem relatively warmer.

In some of the animals, quadruple ligation and excision of the fistula was performed after 4 months. A rise of toe temperature of the fistulous leg was noted on excision of the communication (Fig. 4c). This was probably due to redistribution of arterial blood with a more normal blood flow through the distal capillary beds.

Effects of sympathectomy. After a period of 7 months had been allowed for definite physiologic changes to have taken place, so far as the general and local cardiovascular systems were concerned 7 dogs were selected from the group and repeated preoperative temperature readings were taken (Fig. 5 up to a). Prior to a sympathectomy the animals were given ether anesthesia in an effort to simulate the effects of the operation since Herrick and associates and Baldes and associates had showed that the 2 procedures caused an identical increase in blood flow in the femoral artery of the dog. We soon discovered that under light ether anesthesia there was a lag in vasodilatation in the limb with the fistula, the rise in temperature being only about 2.5 degrees C. instead of the 5.5 degrees C. average of the normal side (Fig. 5a). This lessened response was shown to be a lag rather than organic inability to respond since under deep ether anesthesia (or lumbar sympathetic ganglionectomy) the temperature of the leg with the fistula continued to rise to a total average of 4.5 to 5.0 degrees C. higher than before anes-

DETERLING ET AL. ARTERIOVENOUS FISTULA

Bush (32) have reported cardiac failure in a period of only a few days or weeks after the development of a traumatic fistula. Fick found some of the vascular alterations irreversible and argued for early operation on patients who have arteriovenous fistula. Harbison has similarly urged early operation after employing sympathectomy to increase the collateral circulation so that frequently associated nerve injuries can be repaired easily. Elkin (9, 10) reported early operation to have been performed frequently on soldiers without even sympathetic block being necessary. However, the important effect that sympathectomy exercises on the full development of collateral systems has been emphasized by Mulvihill and Harvey. They concluded that at least the interruption of efferent vasomotor impulses by ganglionectomy initiates the establishment of the collateral circulation and to all appearances in the same manner as it occurs after a time of itself.

The first clinical application of this fundamental principle was reported by Gage (14) in 1933 in the treatment of a mycotic aneurysm of the iliac artery. By paravertebral sympathetic block the circulation in the limb was increased sufficiently to allow ligation of this large vessel with impunity. Subsequently in 1939 (15) he stated that he "had similar and satisfactory results with arterial and arteriovenous aneurysms.

Bird in 1935 was perhaps the first to report the preoperative use of sympathectomy preparatory to the repair of a major peripheral aneurysm. Plotkin in 1939 reported excellent results from lumbar sympathetic ganglionectomy performed in the presence of marked ischemia of the leg 1½ hours after excision of a popliteal arteriovenous fistula. In 1940 Waugh treated an arteriovenous fistula in which the collateral circulation was so poor that sympathectomy was done before excision of the fistula. The patient experienced such symptomatic improvement that he temporarily refused further treatment for the fistula. (Subsequently Waugh has had further recourse to sympathectomy as a preparation for obliterative procedures for arteriovenous fistulas.) In 1943 the "Military manual of traumatic surgery" (35) suggested that in cases of arterio-

venous fistula in addition to the usual methods of treatment, sympathectomy "may be of value. Subsequently a War Department "Bulletin on care of battle casualties" (48) noted that while most arteriovenous fistulas do not require emergency treatment, a certain number must have early surgical treatment in the presence of hemorrhage, impending rupture, paralysis from the pressure on the nerves near the aneurysm or threatened gangrene. It suggests that preoperative and postoperative injections of 1 per cent solution of procaine hydrochloride to block the sympathetic ganglia or sympathectomy may be used in vascular cases to improve circulation by removing vaso-spasm. Recently there have been promising reports by Linton and White, Pugh, Harbison, Kirtley, Mason and Giddings (31), Shumacker and Carter and Freeman in which there was definite evidence of stimulation of collateral circulation in chronic arteriovenous or arterial aneurysms by paravertebral block or sympathectomy. Early operation has been possible and when there was an attendant nerve injury repair of the nerve has been facilitated. Naide has had encouraging results from sympathetic block to supplement anti-toxin and penicillin in gas gangrene infections.

This study has shown that while such a series of sequel to arteriovenous fistula as ischemic gangrene is relatively uncommon there does exist frequently a preoperative and postoperative chronic vascular insufficiency which may be relieved by interruption of the sympathetic vasomotor control. The influence exerted by the earlier investigators in so far as depending on the time factor for the development of collateral circulation is very strong. Elkin (9) in his treatment of 106 patients who had traumatic aneurysms observed in a military hospital has not employed procedures that might be used to stimulate collateral circulation other than intermittent compression before employing obliterative operations. Many competent physicians have gone so far as to declare that attempts to improve circulation in cases of chronic arteriovenous fistula were actually contraindicated.

The results of clinical application of interruption of the sympathetic nerves performed to develop collateral circulation before opera-

olar and capillary beds as a result of removing the arteriovenous communication.

Unilateral sympathectomy—As in the preceding experiment concurrent readings were made of both hind limbs: rectal and air temperatures (Fig 5). These results represent the type of response one may expect in the clinical application of lumbar sympathectomy to patients having arteriovenous fistula of the leg.

The response to ether anesthesia in this series of animals was again identical with that previously described for the animals in other series. Under light anesthesia a lag in the temperature rise was noted in the limb with the fistula compared to the immediate complete response of the control normal limb (Fig 5a). With deep ether anesthesia the temperature continued to rise to a level about 1.0 degree C below that of the normal side (Fig 5a'). At this point left lumbar ganglionectomy was performed.

After recovery from ether anesthesia, the temperature of the control limb fell to the preoperative level or slightly lower, indicating in some instances a contralateral vasoconstriction. This latter phenomenon was only transient, however. On the sympathectomized side the elevated cutaneous temperature persisted at a level of about 37 degrees C. During the subsequent 2 weeks this significant rise of toe temperature was maintained with only a slight decline to about 36.0 degrees C or an elevation of 3.0 to 4.5 degrees C over that of the normal control side (Fig 5a to b). This fact demonstrated conclusively that the vessels distal to the fistula were indeed capable of further vasodilatation even after a period of 7 months in which collateral circulation had developed.

As in the other groups, these animals were given the cool room test: there was only a slight fall of about 1.0 degree C in the temperature of the sympathectomized limb as compared with a decrease of temperature of more than 8 degrees C in the normal limb (Fig 5b). This is clear evidence that an anatomic interruption of the vasomotor nerves had been accomplished by the sympathetic ganglionectomy.

Two animals were selected from this group. Two weeks after the unilateral sympathec-

tomy the fistula was excised by quadruple ligation and excision. Once again a slight but significant rise of toe temperature was observed indicating increased distal arterial flow after obliteration of the fistula (Fig 5c).

Comment—It is evident that our experiments have indicated that the blood flow in a limb may be significantly increased in the presence of a chronic arteriovenous fistula of a major peripheral artery following sympathetic denervation. The adequate treatment of arteriovenous fistula depends primarily on the condition of the collateral blood supply when an obliterative procedure is the method of choice. Naturally the secondary factors of general condition of the patient, his cardiac status and presence of infection or nerve involvement are important but in the presence of insufficient blood supply little choice remains to the surgeon beyond temporary vessel ligation, amputation or in certain cases, restorative endoaneurysmorrhaphy. In any operative procedure in which the arteries are involved one runs the ever present danger of disastrous vasospasm as a result of the surgical manipulation. The present-day safeguards against thrombosis, such as precise aseptic technique, improved antibiotic agents and the anticoagulant drugs, heparin and dicoumarol, have made direct repair or ligation of major peripheral arteries a less formidable procedure than in the past century or even during World War I.

There is considerable evidence both direct and indirect that the majority of channels composing a collateral system are in existence, even though relatively inactive in the normally functioning part. In the dog many investigators have demonstrated by arteriography the ready appearance of supplementary arterial channels when obstruction had occurred in various regions. Vvedenski in the hind limb, Kolesnikov in the fore limb, Andreyev in the head.

The demonstration of the great differences in the arterial and arteriovenous bed in the limbs of our animals that had fistulas raises the question whether a surgeon is justified in waiting several months for collateral circulation to develop before closure of a fistula in a patient. Mason (30) and Mason, Graham and

A NEW OPERATIVE TREATMENT FOR ELEPHANTIASIS

EDGAR J POTH M.D. Ph.D., F.A.C.S., SAM R. BARNES, M.D., and
GRIFF T ROSS M.D. Galveston, Texas

WE shall not consider the various etiological factors of elephantiasis (Matas 1913) but shall concern ourselves with the late stage of persistent irreversible edema with fibrosis of the subcutaneous tissues and derma in those instances or recurrent erysipieloid infections due to lymphatic obstruction.

Homans (1928) Homans and Zollinger (1929) Homans Drinker and Field (1934) Reichert (1926 1927 1930) and many others have treated this subject experimentally and clinically. It has been concluded that the most satisfactory treatment of this malady is the complete removal of the lymphatic bearing tissues especially of the legs and occasionally of the thighs. Of the various procedures used to accomplish the removal of these tissues the Kondoleon (1912) operation of excising segments of skin and the underlying fibrous connective tissues extending down to the

muscles or by the undercutting of thin skin flaps and excising the lymphatic bearing subcutaneous tissues (Sistrunk 1927) have been used most extensively and are considered as giving the best results. These procedures are multiple time-consuming operations requiring long hospitalization. The condition frequently recurs or is not relieved. In a true elephantiasis with progressive fibromatosis as defined by Matas, the lymphatics of the derma are involved in addition to those of the subcutaneous tissue.

This paper describes a single operation for the removal of the lymphoid bearing tissues. The procedure is simply the excision of all tissues down to the sheaths of the muscles of the thigh and leg excepting a narrow strip covering the tibia anteriorly and then grafting the denuded surface with thick split grafts.

Alternate procedures are illustrated in Figures 1 and 2.

CASE REPORT

C. M., No. 275574, white male aged 34 years was first observed to have an enlarged left leg at the age of 2 months which was subsequently diagnosed as

From the Department of Surgery University of Texas, Medical Branch, Galveston, Texas.

Presented at the forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Fig. One stage operation for elephantiasis. A, The incisions are outlined so as to preserve full thickness of tissue over the tibia. B, If the condition of the skin is satisfactory, thick split grafts are cut before the tissues are dissected from the operative field. Grafts are cut from the entire circumference except for the narrow strip over the

tibia. C and D show the remaining derma and subcutaneous tissues being excised down to muscle with preservation of a strip of tissues over the tibia. E and F illustrate the situation after grafting with split skin grafts. Note: If indicated, the subcutaneous tissue over the tibia could be excised after healing has occurred.

Fig. 2. An alternate two stage operative procedure. Illustrations A, B and C show the removal of the subcutaneous tissue from the area covering the tibia. Illustrations D, E, F and G show the completion of the operation after the flap over the tibia has healed and a new blood supply has been established.

milroy's disease. The enlargement and edema have increased progressively with recurrent attacks of erysipeloid infection, pain, and fever. A Kondoleon operation in 1935 gave temporary improvement. Daily baths followed by sponging with 1:4000 zephiran solution as a preoperative measure succeeded in clearing the left leg of numerous small furuncles. The skin of the leg was thickened but still retained some elasticity. It was decided to cut split grafts from this surface before excising the remaining skin and subcutaneous connective tissues down to the muscle sheath, and to use these grafts to cover the dissected area. A strip of skin and subcutaneous tissue was left to cover the tibia anteriorly (Figure 1). If the local skin is not suitable for transplantation other donor sites should be selected. It is questionable whether the local skin should ever be used because the lymphatic vessels of the derma are involved in elephantiasis.

The skin grafts were dressed with glycerine con-

taining zephiran in 1:1000 concentration (Poth 1945). Postoperative course was uncomplicated. Dressings were first changed on the twelfth post operative day. The appearance 3 weeks and 3 months postoperatively is shown in Figures 5 and 6.

The patient has been relieved of his disability and is working as a laborer. The edema of the foot has become progressively less. A year has passed without recurrence of infection. While no supportive dressing has been worn by this patient, it is desirable to use an elastic bandage or stocking for a year to 18 months following operation.

DISCUSSION

Many patients with elephantiasis are incapacitated by the enlarged limb. The operation outlined here causes considerable disfigurement and should not be undertaken early.

Fig. 3. The tissue excised weighed 2150 grams. A, left, shows the rolled specimen from which split grafts were cut. B, shows the deep surface.

INDICATIONS FOR PORTACAVAL ANASTOMOSIS— ANALYSIS OF CASES

ARTHUR H. BLAKEMORE, M.D. New York, New York

THE first anastomosis to join the portal and caval system of veins was made in 1877 by Von Eck, a Russian physiologist. His operation upon dogs, anastomosing the portal vein to the vena cava, side-to-side, became widely known as the Eck fistula. Surgeons early recognized the rationale of establishing portacaval shunts for the relief of portal hypertension and over the years from 1903 to 1914 occasional case reports appeared in the literature (3, 4).

That severe portal hypertension may cause gastrointestinal hemorrhage has long been known, but the rôle of portal hypertension in conjunction with deranged blood proteins in association with ascites is more recently better understood. In an experience covering the completion of 23 portacaval anastomoses with follow up observations, some data having bearing upon the selection of cases for operation have been accumulated. Since the portacaval shunt affords a rational approach to the control or amelioration of hemorrhage due to portal hypertension I will first discuss indications for its use for this purpose.

Patients with congestive splenomegaly exhibiting Banti's syndrome who give a history of one or more episodes of gastrointestinal bleeding but whose liver function tests are essentially normal may be classified as cases of portal hypertension due to extrahepatic portal block. Such patients are candidates for a portacaval shunt. In the majority of these cases the portal block is due to cavernomatous transformation or atresia of the portal vein. Since it is not feasible to anastomose the portal vein to the vena cava in the above type of case the splenic vein to renal vein becomes the portacaval anastomosis of choice in this group. It is the surgeon's responsibility in dealing

with such cases to be prepared to perform a splenorenal anastomosis before proceeding with a splenectomy. Venous pressure readings, properly taken at operation, are an indispensable aid in localizing the site of obstruction in the portal radicals. It is now an established fact that splenectomy alone for congestive splenomegaly will cure only that relatively small group of cases of thrombosis of the splenic vein in which the site of obstruction is distal to the junction of the coronary vein. In such cases venous pressure readings taken from known branches of the superior mesenteric and coronary veins are found to be normal.

THE RÔLE OF THE PORTACAVAL SHUNT IN PORTAL CIRRHOSIS OF THE LIVER

The very fact that hemorrhage or ascites or both can occur in cirrhosis cases purely on the basis of extremely depressed liver function places a great responsibility upon the surgeon in the selection of cases for the portacaval shunt operation. I will cite cases to illustrate this point.

The first case was that of the wife of a physician whose first complaint was uterine bleeding. A dilatation and curettage revealed no cause for the bleeding and finally during the performance of a hysterectomy cirrhosis of the liver was discovered. Subsequent liver function and chemistry studies revealed a badly decompensated liver. The prothrombin time was markedly elevated. The patient's general condition progressively deteriorated. Some 3 months later she experienced her first episode of gastrointestinal hemorrhage. Over a period of 5 months the patient was continuously confined in the hospital suffering repeated hematemeses occurring at monthly intervals. Finally the patient was placed upon a high protein high carbohydrate diet with large doses of vitamin B complex. Gradually her appetite and strength improved. Some 4 months later following a 6 weeks vacation in Florida the patient was admitted to the Presbyterian Hospital for study. The liver was found to be rather hard and enlarged. There was no ascites present. Esophagograms revealed small esophageal varices. The blood proteins

BLAKEMORE INDICATIONS FOR PORTACAVAL ANASTOMOSIS

summarized and clarified by classifying cases of cirrhosis in three groups as follows: Group I, cases in which ascites or a tendency to hemorrhage is based on the inability of the damaged liver to form albumin or prothrombin in adequate amounts. Portacaval anastomosis is not indicated in this group. Group II cases of cirrhosis in which the liver function is adequate to furnish the required amount of albumin and prothrombin but as a result of fibrotic contraction and periportal fibrosis a severe degree of portal hypertension has supervened. Wasting ascites and severe hemorrhage can be controlled in this group only by the portacaval shunt. Group III cases of cirrhosis having varying degrees of depressed liver function plus evidence of considerable elevation of the portal pressure. Such cases are candidates for the portacaval shunt operation but the question is when. It is our present policy to study the individual case with exceeding care when ever possible over a sufficient period of time to become thoroughly familiar with the behavior of the liver before bringing the case to operation. This is usually possible even in patients who have been subject to recurring hemorrhages. The idea is to improve liver function to its maximum employing a comprehensive liver regimen energetically applied for as long a period as necessary.

DISCUSSION

The portacaval shunt operation is indicated and affords a chance of ultimate survival for cases of Banti's syndrome with extrahepatic portal block cases in which there is hypertension in the coronary or portal veins.

The portacaval shunt has an equally important rôle in the treatment of portal hypertension due to cirrhosis of the liver. But, its application must be decided on the basis of portal hypertension being the primary cause of hemorrhage or ascites in the individual case.

ANALYSIS OF CASES

The portacaval shunt operation has been completed in 23 cases. There have been 4 postoperative deaths.

Hemorrhage from a sizable collateral vessel discovered at the conclusion of an anastomosis of the portal vein to vena cava accounted for

death in a case of cirrhosis of the liver. One cirrhotic patient died of cholemia 4 days following the establishment of a splenorenal shunt. Another cirrhotic patient died also of liver failure 6 days following the establishment of a portal vein to vena cava anastomosis. The fourth death resulted from mesenteric thrombosis occurring on the 14th day following a splenorenal anastomosis. The first death was the result of technical error. Death from liver failure in the 2 cirrhotic patients involves essentially errors in judgment in the selection of cases. Whereas mesenteric thrombosis is in the lap of the gods!

Patients have been explored in whom it was not feasible to accomplish a shunt operation. The majority of these patients had been subjected to a previous splenectomy. Of the 23 cases in which portacaval shunts were completed there were 15 patients who had anastomosis of the splenic vein to the renal vein following splenectomy and left nephrectomy. One of these patients had had a splenectomy at a previous operation. In one other post splenectomy bleeder it was possible to anastomose the stump of the splenic vein to the vena cava end to-side, by suture.

Anastomosis of the portal vein to the vena cava end to-side, was carried out seven times. A 12 millimeter vitallium tube was used four times (1) a 10 millimeter once and an 8 millimeter vein lined tube once and suture anastomosis once.

Seventeen of the 19 patients surviving operation have a follow up exceeding 6 months. Two deaths have occurred: one a child having portal cirrhosis, died some 2 years 4 months postoperatively of uremia due to polycystic disease of the kidney; the second case a man with bad portal cirrhosis, died 1 year following operation of cholemia. A necropsy examination was made in each case. In the child the splenorenal shunt had become occluded. This outcome was not unexpected because at operation in this, our first case there was considerable angulation of the splenic vein over the funnel edge of the vitallium tube. The splenorenal anastomosis in the second case was found to be patent.

Five additional patients with bad cirrhosis of the liver have been followed (2 cases 2

Fig 1. Case 536859. a, left, Infrared photograph. Note distention of abdomen with ascites, umbilical hernia and the presence of superficial collateral veins. b, Same patient 5 months after the establishment of a splenorenal shunt. The ascites has completely disappeared.

years each 3 cases $1\frac{1}{2}$ years each) All for the most part, have done satisfactorily considering their preoperative status. All of the patients are active and 4 of the 5 are working. There was delay in disappearance of ascites following operation in 1 a minor bleeding episode in another.

I should like to discuss in more detail a sixth case, a patient with extrahepatic portal vein obstruction and biliary cirrhosis who has been followed now 2 years since the establishment of a splenorenal shunt.

CASE 536859. The question of performing a portacaval shunt procedure on this 46 year old man arose during an admission for hematemesis in November 1944. This was his 10th admission to the Presbyterian Hospital over a 7 year period.

His initial troubles began with an impacted gall stone causing cicatricial stenosis of the distal common duct and fibrotic pancreatitis. The latter caused partial obstruction of the duodenum and finally obstruction of the portal vein. As corrective measures, a gastroenterostomy and a cholecystic fistulostomy were performed. Some 5 years later because of recurring attacks of jaundice cholangitis, and a persistently high alkaline phosphatase, an

operation connecting the proximal end of the common duct to the pylorus using a vitallium tube was performed. In spite of this procedure over the next 3 years this patient's health continued to deteriorate. There was progressive loss of strength appetite, and weight. The episodes of cholangitis recurred in spite of long periods of therapy with sulfadiazine. The liver remained large with laboratory evidence of progressive cirrhosis. The spleen became more and more enlarged *pari passu* with the development of prominent superficial veins over the abdomen. Finally esophagograms revealed the presence of varices. Ascites supervened. Over an 8 month period prior to this admission the patient suffered five episodes of severe gastrointestinal hemorrhage.

On November 30, 1944, a splenorenal portacaval shunt employing a vein graft with two 5 millimeter vitallium tubes was carried out. Following the above procedure there was a reduction in size of the superficial abdominal veins. The ascites, which had been present for some 8 months before operation, gradually disappeared. Over the first 10½ months following the establishment of the portacaval shunt, the patient gained 22 pounds. His appetite and digestion were excellent. He was working daily until October 12 1945 when he caught cold. Following a severe coughing attack the patient had abdominal pain and 2 days later the patient passed 2 or 3 tarry stools. This episode cleared promptly however

BLAKEMORE INDICATIONS FOR PORTACAVAL ANASTOMOSIS

with a rapid return of strength and appetite. Some 3 months later in January 1946 the patient began to have gas on the stomach with upper abdominal pain. The pain was relieved temporarily by eating or the ingestion of alkalis. One month later (February 1946) the patient again passed a few tarry stools. He was hospitalized for a short while during which he recovered his strength from intermittent abdominal pain. A month later (March 25, 1946) the patient was admitted for his third episode of tarry stools since the portacaval shunt operation. Because of the persistence of intermittent attacks of abdominal pain favorably affected by the ingestion of food or alkali the presence of a marginal ulcer was considered but not proved by x ray. Nevertheless this patient's stools did not become guaiac negative until after the administration of amphotel therapy during which time the attacks of abdominal pain entirely disappeared. The patient has continued free of digestive symptoms or pain now some 6 months during which there has been no recurrence of bleeding from the gastrointestinal tract.

See Figure 1: infrared photographs a before operation b 5 months after operation.

This patient has had three episodes of gastrointestinal bleeding since operation. Three possible causal factors may be discussed in explaining the recurrence of bleeding.

- 1 Occlusion of the anastomosis: a femoral vein graft mounting a 5 millimeter vitallium tube on either end was employed to bridge the splenic and renal veins in this case—a technique which combined what we now consider objectionable features, namely the employment of a vein graft and the use of vitallium tubes of a diameter undesirably small. On the other hand there is an extremely good argument against occlusion of the anastomosis as being the cause of the recurrence of bleeding in this case.

- 2 Hemorrhage from a marginal ulcer at an old gastroenterostomy site. Against this as a source of bleeding was the failure to demonstrate a marginal ulcer in this case by x ray. It is of extreme interest, however, that the first bleeding episode to occur following the establishment of the portacaval shunt manifested itself in tarry stools 2 days after the onset of epigastric pain. The patient stated that at the time he had a coryza and a productive cough—the pain following a coughing episode. Three months later the epigastric pain recurred accompanied by the eructation of gas. The ingestion of food would relieve the pain

temporarily. These new symptoms persisted and during the next 3 months occurred the second and third bleeding episodes. The persistence of guaiac positive stools and abdominal pain was protracted until the institution of amphotel therapy following which the pain ceased and the stools rapidly became guaiac negative. The patient's digestion and appetite improved steadily and now 6 months later the patient has gained 18 pounds and his stools remain guaiac negative.

- 3 A third possible explanation for the bleeding in this case is a logical one, namely the rather small (5 mm) vitallium tubes employed may not handle a volume of blood adequate to lower pressure in the portal radicals sufficiently under conditions of sudden straining or possibly in the presence of mucosal ulceration. One look at the size of the collateral veins over this man's abdomen lends distinct credence to this explanation.

Though a splenorenal shunt be not adequate in size to afford total protection against the occurrence of bleeding that does not mean it will not do yeoman service in lessening the number and severity of attacks—a logical explanation of the clinical behavior in this case.

Our experimental evidence and clinical experience indicate that if a blood vessel anastomosis remains patent up to 60 days following operation it is extremely likely to remain open permanently. Here is a man who for 8 months prior to operation had ascites requiring paracentesis. During this period there were 5 episodes of severe gastrointestinal hemorrhage including hematemesis. For a month prior to operation the patient's condition was extremely precarious due to persistent gastrointestinal bleeding. A splenorenal shunt was established at this point. Following operation there was marked clinical improvement. The ascites disappeared and there was a gradual gain in weight of 22 pounds.

It is logical to conclude that the patency of the anastomosis accounted for the disappearance of ascites in this case. The presence of persistent ascites for 8 months prior to operation had been conceded by all to be on the basis of portal vein compression due to a fibrosing pancreatitis. Whereas the patient did have biliary cirrhosis there was never at

Fig Case 536889. a, left, Infrared photograph. Note distention of abdomen with ascites, umbilical hernia and the presence of superficial collateral veins. b, Same patient 5 months after the establishment of a splenorenal shunt. The ascites has completely disappeared.

years each 3 cases $1\frac{1}{2}$ years each) All for the most part have done satisfactorily considering their preoperative status. All of the patients are active and 4 of the 5 are working. There was delay in disappearance of ascites following operation in 1 a minor bleeding episode in another.

I should like to discuss in more detail a sixth case a patient with extrahepatic portal vein obstruction and biliary cirrhosis who has been followed now 2 years since the establishment of a splenorenal shunt.

NOTE. All cases of cirrhosis of the liver

any time evidence of decompensation of the liver. Furthermore up until the time of disappearance of the ascites following the establishment of the portacaval shunt, the patient was not on a liver dietary regimen. In view of the above fact, if the bleeding episode which occurred 10½ months after operation in this man had been due to a sudden closure of the splenorenal shunt one would have expected a prompt return of the ascites. In fact, in a very recent case in which thrombotic occlusion did take place the prompt occurrence of ascites antedated the appearance of esophageal bleeding by 2 weeks.

It seems reasonable that this man's splenorenal shunt may be open but not of a size adequate to shunt enough blood to afford complete protection against hemorrhage. After

all, he has had only three episodes of gastrointestinal hemorrhage in a 24 months post-operative period compared to 5 attacks over an 8 months period before operation. He is free of ascites, and working.

We do not have, as yet, enough follow-up data on portal pressures before and after opening portacaval shunts to predicate what pressure level will afford absolute protection against hemorrhage. However we do have data upon portal pressures to indicate that the splenic vein may not always be of adequate size to afford a shunt sufficiently large to protect against episodes of hemorrhage. As a possible corollary to the importance of the size of the shunt our follow-up has not so far been complicated by hemorrhage in those cases in which direct anastomoses of the portal

terminal illness from liver failure. Whereas it seems likely that a low blood prothrombin level may have contributed to the initiation of hemorrhage, it must be remembered that this patient still had a portal pressure of 240 millimeters of water following opening of the shunt. Before operation the portal pressure was 400 millimeters of water—the highest pressure we have yet recorded on a case of cirrhosis. Though this patient's ascites cleared following operation his jaundice persisted. His terminal illness was ushered in by a high fever from what appeared to be an upper respiratory infection. It is only fair to state at this point, however, that following the establishment of a splenorenal shunt, this man's appetite strength and weight improved. He was able to return for part time work to his job as a barber.

The above case proves that a splenorenal shunt, though patent, may not be of a size adequate to shunt an amount of blood sufficient under all conditions to afford absolute protection against future hemorrhage. Three additional cases over a 2 year follow up period have shown such marked overall clinical improvement following the portacaval shunt operation as to justify including them in the above classification.

One of the cases has already been discussed in detail. One case a girl of 15 years having Banti's syndrome with extrahepatic portal block was found to have a portal pressure of 310 millimeters of water. Following the opening of a splenorenal anastomosis the portal pressure receded to 190 millimeters of water. This patient gained strength and weight following operation but over a 2½ year (30 month) follow-up period she has had three episodes of gastrointestinal bleeding. Two of these hemorrhages were comparatively trivial to the attacks which came regularly at 6 month intervals before operation.

A third case a cirrhotic who gave a long past history of hematemesis, was operated upon following a month's seizure of hemorrhage during which the stools failed to become guaiac negative. Following the establishment of a portacaval shunt, this man's general condition improved markedly. His jaundice gradually improved as well as his liver

function tests. A few months after operation, the patient returned to his job and has been working ever since. Over a 2 year follow-up period this man has had one comparatively minor bleeding episode consisting of 2 or 3 tarry stools.

Finally there are 3 cases in which the evidence points to closure of the portacaval anastomoses. All 3 cases have Banti's syndrome with a past history of frequent episodes of gastrointestinal bleeding including hematemesis. In 1 case that of a 15 year old girl, who 4 years previously had had a splenectomy an anastomosis was effected by suture of the stump of the splenic vein to one branch of the left renal vein. To the other branch of the renal vein (following nephrectomy) the proximal stump of the inferior mesenteric vein was anastomosed employing a 5 millimeter vitallium tube. Thrombotic occlusion of the anastomoses was heralded by the sudden appearance of ascites on the seventh postoperative day. Some 2 weeks later the patient had an attack of hematemesis. The bifurcated renal branches were rather small in this case and in retrospect it would possibly have been better judgment to have been satisfied with one anastomosis.

The second case was that of an 8 year old boy who one year previously had had a splenectomy. The boy had Banti's syndrome complicated by bronchiectasis. During the year following splenectomy the boy suffered 5 episodes of severe gastrointestinal hemorrhage including hematemesis. The proximal stump of the splenic vein was anastomosed to the vena cava by suture end-to-side. During a year following this procedure, as presumptive evidence of closure of the anastomosis, the hemorrhages have recurred with equal frequency and severity.

Finally in a child 3 years of age an end-to-end suture of the splenic vein to the renal vein has failed to lessen the tendency to hemorrhage over a year's follow up period.

SUMMARY

In presenting the rationale of the portacaval shunt for the relief of portal hypertension, special stress is placed upon the selection of cases.

BRANTIGAN ANOMALIES OF PULMONARY VEINS

An analysis of 23 cases having portacaval anastomosis was presented

The procedure is presented as the one hope of relief for those cases with Banti's syndrome who have essentially normal livers but present the problem of control of gastrointestinal hemorrhage

The importance of exercising extreme care and judgment in the selection of cases of cirrhosis for operation and the reasons thereof are discussed

ANOMALIES OF THE PULMONARY VEINS

Their Surgical Significance

O. C. BRANTIGAN M.D. F.A.C.S., Baltimore, Maryland

THE reports of anomalies of the pulmonary veins are appearing more frequently in the medical literature. In the past all descriptions and case reports have come from autopsy material or from studies made in the anatomic laboratory. This article will describe and discuss anomalies of the pulmonary veins found at the time surgical operations were being performed upon the lungs.

Brody made a review of the literature and in 1942 presented an excellent discussion of the subject. The final study included 106 patients. Since 1942 seven different authors have reported 14 additional cases (3, 4, 7, 8, 10, 11, 12). Brody classified the anomalous venous drainage from the lungs as (1) total drainage into the right atrium or its tributaries 36 per cent and (2) incomplete drainage into the right atrium or its tributaries 64 per cent. When the venous drainage from the lungs into the right atrium or its tributaries is incomplete the most common site for drainage in order of frequency is the superior vena cava, right atrium and the left innominate vein. The right pulmonary vein is anomalous in its drainage twice as frequently as the left.

Anomalous pulmonary veins have been described as draining into the following: superior vena cava, right atrium, left innominate vein, coronary sinus, inferior vena cava, azygos vein, left subclavian vein, portal vein and persistent left superior vena cava.

It has been suggested that if less than 50 per cent of the pulmonary blood is abnormally shunted into the major venous system or into the right side of the heart, the patient is unlikely to develop cardiac decompensation. Such an assumption is based upon a normal heart. Hughes and Rumore were the first to give actual figures that might indicate the quantity of pulmonary blood that flows abnormally into the major venous system from an anomalous pulmonary vein. Both of the patients they described died of cardiac failure and both had rheumatic heart disease. By comparison of the cross-sectional area of the anomalous veins with the cross-sectional area of the normal pulmonary veins they calculated that in one patient 26 per cent and in another 20 per cent of the pulmonary blood was shunted into the major venous system. It is difficult to calculate the effects of this additional effort upon the already injured heart. Conant and Kurland described a patient who tolerated extensive tuberculosis in the left lung but died rapidly when the right lung became infected. At autopsy it was found that

terminal illness from liver failure. Whereas it seems likely that a low blood prothrombin level may have contributed to the initiation of hemorrhage it must be remembered that this patient still had a portal pressure of 240 millimeters of water following opening of the shunt. Before operation the portal pressure was 400 millimeters of water—the highest pressure we have yet recorded on a case of cirrhosis. Though this patient's ascites cleared following operation his jaundice persisted. His terminal illness was ushered in by a high fever from what appeared to be an upper respiratory infection. It is only fair to state at this point, however that following the establishment of a splenorenal shunt, this man's appetite strength, and weight improved. He was able to return for part time work to his job as a barber.

The above case proves that a splenorenal shunt, though patent, may not be of a size adequate to shunt an amount of blood sufficient under all conditions to afford absolute protection against future hemorrhage. Three additional cases over a 2 year follow up period have shown such marked overall clinical improvement following the portacaval shunt operation as to justify including them in the above classification.

One of the cases has already been discussed in detail. One case, a girl of 15 years, having Banti's syndrome with extrahepatic portal block was found to have a portal pressure of 310 millimeters of water. Following the opening of a splenorenal anastomosis the portal pressure receded to 190 millimeters of water. This patient gained strength and weight following operation but over a 2½ year (30 month) follow up period she has had three episodes of gastrointestinal bleeding. Two of these hemorrhages were comparatively trivial to the attacks which came regularly at 6 month intervals before operation.

A third case a cirrhotic who gave a long past history of hematemesis, was operated upon following a month's seizure of hemorrhage, during which the stools failed to become guaiac negative. Following the establishment of a portacaval shunt, this man's general condition improved markedly. His jaundice gradually improved as well as his liver

function tests. A few months after operation, the patient returned to his job and has been working ever since. Over a 2 year follow up period this man has had one comparatively minor bleeding episode consisting of 2 or 3 tarry stools.

Finally there are 3 cases in which the evidence points to closure of the portacaval anastomoses. All 3 cases have Banti's syndrome with a past history of frequent episodes of gastrointestinal bleeding including hematemesis. In 1 case that of a 15 year old girl, who 4 years previously had had a splenectomy an anastomosis was effected by suture of the stump of the splenic vein to one branch of the left renal vein. To the other branch of the renal vein (following nephrectomy) the proximal stump of the inferior mesenteric vein was anastomosed employing a 5 millimeter vitallium tube. Thrombotic occlusion of the anastomoses was heralded by the sudden appearance of ascites on the seventh postoperative day. Some 2 weeks later the patient had an attack of hematemesis. The bifurcated renal branches were rather small in this case and in retrospect it would possibly have been better judgment to have been satisfied with one anastomosis.

The second case was that of an 8 year old boy who one year previously had had a splenectomy. The boy had Banti's syndrome complicated by bronchiectasis. During the year following splenectomy the boy suffered 5 episodes of severe gastrointestinal hemorrhage including hematemesis. The proximal stump of the splenic vein was anastomosed to the vena cava by suture, end-to-side. During a year following this procedure, as presumptive evidence of closure of the anastomosis, the hemorrhages have recurred with equal frequency and severity.

Finally in a child 3 years of age an end-to-end suture of the splenic vein to the renal vein has failed to lessen the tendency to hemorrhage over a year's follow up period.

SUMMARY

In presenting the rationale of the portacaval shunt for the relief of portal hypertension special stress is placed upon the selection of cases.

BRANTIGAN ANOMALIES OF PULMONARY VEINS

An analysis of 23 cases having portacaval anastomosis was presented

The procedure is presented as the one hope of relief for those cases with Banti's syndrome who have essentially normal livers but present the problem of control of gastrointestinal hemorrhage.

The importance of exercising extreme care and judgment in the selection of cases of cirrhosis for operation and the reasons thereof are discussed

ANOMALIES OF THE PULMONARY VEINS

Their Surgical Significance

O C. BRANTIGAN M.D., F.A.C.S. Baltimore, Maryland

THE reports of anomalies of the pulmonary veins are appearing more frequently in the medical literature. In the past all descriptions and case reports have come from autopsy material or from studies made in the anatomical laboratory. This article will describe and discuss anomalies of the pulmonary veins found at the time surgical operations were being performed upon the lungs.

Brody made a review of the literature and in 1942 presented an excellent discussion of the subject. The final study included 106 patients. Since 1942 seven different authors have reported 14 additional cases (3, 4, 7, 8, 10, 11, 12). Brody classified the anomalous venous drainage from the lungs as (1) total drainage into the right atrium or its tributaries, 36 per cent, and (2) incomplete drainage into the right atrium or its tributaries 64 per cent. When the venous drainage from the lungs into the right atrium or its tributaries is incomplete, the most common site for drainage in order of frequency is the superior vena cava, right atrium and the left innominate vein. The right pulmonary vein is anomalous in its drainage twice as frequently as the left.

Anomalous pulmonary veins have been described as draining into the following superior vena cava, right atrium, left innominate vein, coronary sinus, inferior vena cava, azygos vein, left subclavian vein, portal vein and persistent left superior vena cava.

It has been suggested that if less than 50 per cent of the pulmonary blood is abnormally shunted into the major venous system or into the right side of the heart, the patient is unlikely to develop cardiac decompensation. Such an assumption is based upon a normal heart. Hughes and Rumore were the first to give actual figures that might indicate the quantity of pulmonary blood that flows abnormally into the major venous system from an anomalous pulmonary vein. Both of the patients they described died of cardiac failure and both had rheumatic heart disease. By comparison of the cross-sectional area of the anomalous veins with the cross sectional area of the normal pulmonary veins they calculated that in one patient 26 per cent and in another 20 per cent of the pulmonary blood was shunted into the major venous system. It is difficult to calculate the effects of this additional effort upon the already injured heart. Conant and Kurland described a patient who tolerated extensive tuberculosis in the left lung but died rapidly when the right lung became infected. At autopsy it was found that

the blood from the left lung drained anomalously and completely into the left innominate vein. Disease of the nonfunctioning lung caused little embarrassment to the patient, but disease of the functioning lung was rapidly fatal. Thus, the physiologic effect of pulmonary blood shunted into the major venous system will be influenced by disease in the functioning lung or by disease of the heart.

The seemingly wide and unrelated variations that occur in pulmonary venous anomalies have been studied from the embryologic point of view in an endeavor to simplify and correlate the anomalies encountered. Brown reviewed the research that had been done on the development of the pulmonary veins and wrote it is evident that (1) The anlage of the vein and its connections with sinus venosus has not been described in detail and (2) the method by which the vein changes its orifice in the center of the sinus venosus for one in

that position of the sinus which lies to the left of the left sinus valve has not been considered. In addition the general relation which the pulmonary venous system bears to the systemic has been entirely neglected in the study of the embryology of the vein." In the 4.5 millimeter cat embryo he reported "At this stage the pulmonary vein exists as a single vessel having two main vascular connections, (1) ventrally a single rounded orifice in the sinus venosus (Fig. 1) and (2) dorsally a connection with that portion of the splanchnic plexus which is pushed forward by the growing pulmonary anlage which it joins at the ventral pole of the lung bud. Thus, the pulmonary venous plexus through the splanchnic venous plexus is connected with the primitive major venous system by the way of both the precardinal and postcardinal veins. In the 6.5 to 7 millimeter embryo he further related "The sinus venosus with the exception of the openings of the cornua has been incorporated into the auricle. The right valve of the sinus is very prominent and is continued into the septum spurium which has shifted to the left and fused with the septum superius. The left valve of the sinus has likewise shifted to the left and its cephalic extremity on the dorsal wall of the auricle has fused with the dorsal caudal portion of the septum superius. As a result of the latter shift the orifice of the pulmonary vein has preceded the left valve of the sinus, passed under the septum superius and now empties into the left auricle having both septum superius and left valve of the sinus or in other words, the interauricular septum on the right. This view is no longer considered to be true in human development. It is thought that the venous plexus covering the primitive lung bud is probably a development from the splanchnic venous plexus (Fig. 2). The pulmonary venous plexus is gathered together into a common pulmonary vein that joins directly and definitively with the left auricle (6 16). Patten in describing human embryology said "Phylogenetically the lungs are relatively new structures. It is not surprising, therefore, that we find the pulmonary veins arising independently and not by the conversion of old vascular channels. They originate as vessels which drain the various branches of

BRANTIGAN ANOMALIES OF PULMONARY VEINS

Fig. 2 A lateral view diagrammatically representing the primitive venous system and the lung bud and its venous plexus. The primitive pulmonary plexus is an outgrowth from the primitive splanchnic venous plexus. The primitive splanchnic venous plexus communicates with the posterior cardinal and postcardinal veins. The pulmonary vein arising from the primitive pulmonary venous plexus will join directly and definitely with the left atrium. This conception of development for the most part is accepted by contemporary embryologists.

Fig. 3 With the exception of the right and left atria, the diagram presents the normal adult structures arising from the primitive venous system. It is viewed from the posterior aspect. If there is a left superior vena cava it is the result of a persistence of the left precardiac vein. The normal remains of the old persistent coronary sinus is the normal remains of the small coronary vein on the left side. If the pulmonary blood is drained abnormally into the right atrium or its tributaries it will drain into one of the structures indicated on this diagram.

the lung bud and converge into a common trunk entering the left atrium dorsally. In the growth of the heart this trunk vessel is gradually absorbed into the atrial wall until usually 4 of its original branches come to open into the left atrium as the pulmonary veins of the adult. Less than the usual amount of resorption of the primitive common pulmonary vein not infrequently results in the pulmonary veins from the right and the left lungs entering the left atrium as single instead of the usual paired vessels (Fig. 4). In continuation of the discussion Pitten made the statement "Occasionally startling anomalous connections of the pulmonary veins are seen such as

the entrance of one of them into the superior vena cava the left innominate or the azygos. Such conditions are explicable only on the basis of exceedingly early embryonic stages in which the developing foregut trachea and lung buds are supplied by a common plexus of small channels which thread in all directions through the loose mesenchyme and communicate with the primitive cardinal veins freely in many places (Fig. 2). With the enlargement of certain channels in the primordial vascular bed to form pulmonary veins leading to the left atrium the primitive connections with the cardinal veins ordinarily disappear. The unusually strong development of some one of these early channels and its retention by the adult derivative of the particular part of the cardinal system involved is behind the occurrence of these abnormal pulmonary connections."

The primitive venous system consisting of the cardinal veins and sinus venosus give rise

Fig. 4. The method of development of an abnormal number of pulmonary veins entering the left atrium is indicated by the diagrams A to G. The dorsal aspect is presented. The primitive pulmonary vein enters the left atrium as a single venous trunk. The primitive single venous trunk is divided into right and left pulmonary veins, A. The right and left pulmonary veins are divided into two veins, B. There is resorption of the venous trunks into the wall of the left atrium until in the normal adult atrium four pulmonary veins open separately into the posterior aspect of the atrium, C. If the right pulmonary vein divides into three branches, D, one for each lobe, close to the atrium they will be resorbed into the atrial wall, thus giving rise to three separate openings on the right side E. If the left pulmonary vein divides into two branches at a greater than normal distance from the atrial wall F they will not be taken up into the atrium and thus only one orifice will open into the atrium on the left, G.

in the adult to the right and left innominate veins, the coronary sinus, the azygos vein, the superior vena cava, the portion of the inferior vena cava adjacent to the atrium, a part of the right atrium and a portion of the portal vein adjacent to the liver. Abnormalities in the persistence of the cardinal veins may give rise in the adult to abnormal azygos veins and to a left superior vena cava (13, 14). When there is anomalous drainage of blood from the lungs, according to all past reports, it has drained into one of the structures above named. Abnormal sites of drainage of pulmonary blood at first glance seem unpredictable but actually they are rather normal from the embryologic point of view. This blood will always drain into some structure originating from the primitive venous system (Fig. 3).

If the early pulmonary veins once drained into the sinus venosus an abnormal shift of its final drainage point could easily account for an abnormal pulmonary drainage into any of the structures originating from the primitive venous system and especially the emptying of pulmonary veins into the right atrium.

Should the pulmonary veins originate from the splanchnic venous plexus (Fig. 2) and then drain first and definitively into the left atrium, certain early connections of the splanchnic venous plexus with the cardinal venous system may persist and thus account for the anomalous drainage of pulmonary blood into any part of the major venous system originating from the primitive venous system. If there is failure of junction of the early pulmonary vein with the left atrium then all blood from the lungs must find an anomalous pathway for drainage. Thus, all anomalies that have been described can be accounted for whether one accepts the old or the new embryologic theory of pulmonary vein development (Fig. 1, 2, 3 and 4).

Embryologists seem to agree upon the essential method of development of multiple openings of the pulmonary vein into the left atrium. The method is described adequately in the quotation from Patten. The various anomalous openings and their method of development have been indicated by the diagrams in Figure 4.

BRANTIGAN ANOMALIES OF PULMONARY VEINS

In the last 3 years pulmonary venous anomalies have been recognized by the author at the operating table. While undergoing pneumonectomy 3 patients were found to have only one pulmonary vein on the left side. Thus, to remove the left lung only one pulmonary vein was ligated. In each patient the single vein was ligated as it entered the pericardium. During pneumonectomy 2 other patients presented 3 pulmonary veins on the right side, or an individual vein for each lobe of the lung on the right side. Upon removal of the lung in these 2 patients 3 veins were ligated as they entered the pericardium. In 1 patient where the right lung was removed for tuberculosis the pulmonary vein from the upper lobe of the right lung drained into the inferior part of the superior vena cava. The pulmonary vein from the middle and lower lobes of the right lung drained into the left auricle. While doing a closed intrapleural pneumonolysis on the left side a pulmonary vein from the upper lobe of the left lung was found draining into the left innominate vein. Since this lung was not removed and since it was viewed through a thoracoscope the interpretation may be erroneous.

When the various anomalies of the pulmonary veins are understood it is reasonable to expect that they will be recognized with greater frequency at the operating table. It is evident that these anomalies are of considerable surgical importance. This importance is mitigated by rarity and enhanced by common occurrence.

Pulmonary vein anomalies can be classified into two groups (1) an abnormal number of pulmonary veins emptying into the left atrium (2) abnormal drainage of the pulmonary veins (a) partial drainage into the right atrium or its tributaries (b) total drainage into the right atrium or its tributaries.

In performing a lobectomy by means of the individual ligation technique the presence of more than a single pulmonary vein must be demonstrated in order to avoid devitalizing the whole lung. When 3 veins are present on the right side the ligation of the vein draining the lobe is facilitated. The variable number of veins that may be found draining the lung is well recognized and described in the standard

textbooks of anatomy (95). If the pulmonary veins were inspected inside the pericardium it seems reasonable to expect that a single pulmonary vein on either side would be of more common occurrence.

It has been recognized that the drainage of pulmonary blood into the major venous system or into the right atrium is a burden upon the heart. The thoracic surgeon endeavors to conserve healthy lung tissue when resection of the lung is necessary. It is important to recognize pulmonary venous anomalies when the thorax is open, since the removal of such a lobe of the lung would be beneficial to the patient by eliminating the burden placed upon the heart. Lobectomy of the lower lobe is more common than lobectomy of the upper lobe of the lung. If the pulmonary vein of an upper lobe drains into the major venous system and the normally draining lower lobe is removed it will increase the relative percentage of pulmonary blood drained into the major venous system. Accordingly it will increase the cardiac burden and should be removed. The most common anomalous pulmonary venous drainage is the drainage of the pulmonary vein from the upper lobe of the right lung into the superior vena cava.

For the thoracic surgeon it is frightening to contemplate the possibility of removing one lung only to find that the other lung drained its blood into the major venous system as in the patient described by Conant and Kurland. Fortunately the drainage of one lung into the major venous system is uncommon. Judged from case reports it occurs about as often as drainage of the total pulmonary blood into the right atrium or its tributaries. Actually, 31 such cases have been reported.

In the past a diagnosis of total drainage of pulmonary venous blood into the right atrium or its tributaries has not been made before death. In such patients death usually comes with the closure of the foramen ovale. It is not unreasonable to believe that some day the condition will be diagnosed before death. If that were possible it would be interesting to speculate upon an operative attack. The interatrial septum might be removed or a major pulmonary vein could be anastomosed to the left atrium.

CONCLUSIONS

1 The anomalous drainage of pulmonary blood is being recognized with increasing frequency

2 When there is anomalous drainage of blood from the lung it drains into some structure arising from the primitive venous system.

3 An anomalous number of pulmonary veins draining into the left atrium is not uncommon and is recognized by the standard textbooks of anatomy

4 In the individual ligation technique for lobectomy of the lung it is important to demonstrate the presence of more than one pulmonary vein if devitalization of the whole lung is to be avoided.

5 If there is anomalous drainage of pulmonary blood into the major venous system the patient will be benefited by removal of the portion of lung thus drained

THE USE OF VASODILATION IN THE TREATMENT OF VENOUS THROMBOSIS

ALTON OCHSNER, M.D., F.A.C.S. New Orleans, Louisiana

THE rationale for vasodilatation obtained by sympathetic block in the treatment of venous thrombosis is that in true thrombophlebitis because of the irritative lesion within the vein impulses are set up and carried over the sympathetic nervous system to the arterioles and venules resulting in severe spasm. As we have emphasized previously (10-15) it is imperative to differentiate between two types of venous thrombosis one in which the thrombus is associated with and is dependent upon an inflammation of the vein wall i.e. thrombophlebitis and another in which the clot is a coagulation thrombus and occurs not as a result of an inflammatory process in the vein wall but because of two other factors a predisposing one consisting of increased coagulability of the blood caused by tissue damage and another, a precipitating one consisting of circulatory stasis which determines the site of the thrombus. These two types of venous thrombosis must be differentiated not only from an etiologic standpoint but also from the standpoint of their clinical manifestations their prognosis, and their treatment. Pathologically the clot in thrombophlebitis is a white or mixed thrombus. It is firmly attached to the vein wall and will not become detached. For this reason there is little or no danger of embolism except in the rare instance in which there is suppuration and in which because of liquefaction of the clot infected emboli can become detached. On the other hand in phlebothrombosis the clot is a red or coagulation thrombus. It is not firmly attached to the vein wall and can become detached easily. The patient with phlebothrombosis is a potential fatality and, although the symptoms

are minimal or lacking there is great urgency for radical therapy. The symptomatology of the two conditions are entirely different. The patient with thrombophlebitis has definite symptoms which vary according to the location whether the deep or the superficial veins are involved. In femorofacial thrombophlebitis which is the most frequent type and which is a typical example of phlegmasia alba dolens the symptoms are maximal. There is pain and fever and the extremity is swollen white and cold. The significance of the paradoxical whiteness and coldness of an extremity in an individual with pyrexia and whose surface temperature elsewhere is increased was not previously appreciated, but is now known to be due to concomitant spasm of the arterioles. These patients although having marked symptoms, do not succumb to the disease but unless adequate therapy is instituted early have persistent sequelae which last for years months or even for the duration of their lives. In the relatively rare case of superficial thrombophlebitis there is also pain and fever. Instead of the extremity being white and swollen as it is in the deep thrombophlebitis there is redness over the involved vein and there is minimal swelling. Superficial thrombophlebitis is usually seen in conjunction with varicose veins or is associated with peripheral arterial disease.

Whereas it is our belief that the treatment of phlebothrombosis consists of radical surgery i.e. ligation of the vein above the site of the thrombus or thrombectomy and ligation after removal of the thrombus, the treatment of thrombophlebitis should be conservative with the exception of the relatively rare case in which there is suppuration.

At the outset it should be emphasized that the treatment of venous thrombosis should consist principally of prophylaxis, and it is our belief that in most instances venous thrombosis can be prevented by the minimization of

Presented at the symposium on Venous Thrombosis and Prevention of Pulmonary Embolism before the Clinical Congress of the American College of Surgeons, Cleveland, December 16-17, 1946.

Fig. 1. Diagrammatic illustration showing the effect of experimentally produced thrombophlebitis on arteriolar pulsation. a, The normal findings in the veins, the arteries, and the arterial pulsations as determined plethysmographically. b, The decrease in the size of the arterioles following ligation of the common femoral vein. This results in a decrease in the arteriolar pulsations. c, A marked decrease in the size of the arteriole and a marked diminution in the arteriolar pulsation, following the production of chemical thrombophlebitis produced by injecting 40 per cent sodium salicylate into the isolated segment of vein. d, The return to normal of the lumen of the arteriole and the arteriolar pulsations following the blocking of the sympathetic impulses originating in the thrombophlebitic segment. This interruption is produced by anesthetization of the sympathetic ganglion.

trauma and infection and by the speeding of the circulation in the veins of the lower extremity venous thrombosis can be greatly minimized. Only after thrombosis has occurred is it necessary that active therapy be instituted. It is a rule on our service that in all patients past forty years of age who have any tissue injury operative accidental during delivery or as the result of destruction of tissue by neoplastic disease or infection the lower extremities are wrapped with compression bandages (Ace No. 8) from the toes to the groin in order to increase the rate of blood flow through the deep venous system. The patient is also made to contract the muscles of the calf and the thigh. Tight abdominal bandages are avoided and the return flow of blood through the venous system to the chest is favored by having the patient take deep breaths. Those positions such as the Fowler's position which favor circulatory retardation of the lower extremity are avoided.

Thrombophlebitis of the deep venous system, particularly the femorotibial, is an interesting biologic phenomenon, because although the lesion is in the large deep veins, the symptoms are the result of arteriolar spasm. Where-

as previously it was thought that the pain was due to the inflammatory process in the veins, that the swelling was due to the plugging of the vein by the thrombus, and that the white discoloration was due to the lymphedema, we have been able to demonstrate experimentally and clinically that all of these manifestations are the result of vasospasm. Experimentally DeBakey, Burch, and I (3) showed that in an isolated thrombophlebitic segment of vein, impulses originate and are carried over the sympathetic nervous system producing spasm of the arterioles of the homolateral extremity (Fig. 1). Subsequently we (16) showed in clinical cases of phlegmasia alba dolens that there is a very definite diminution in the arteriolar pulsation of the involved extremity which can be relieved by sympathetic block (Fig. 2). Concomitant with the relief of the vasospasm there are relief of pain, prompt subsidence of the fever and disappearance of the edema. That the edema is not secondary to the mechanical plugging of the vein by the thrombus is demonstrated by the fact that ligating a vein surgically will not produce a similar edema and that the edema in thrombophlebitis will subside quickly following the

OCHSNER VASODILATATION IN VENOUS THROMBOSIS

chemical section of the sympathetics even though the thrombus still remains. The edema in thrombophlebitis and its persistence are undoubtedly due to the associated vasospasm of the homolateral arterioles, resulting in such a marked diminution in blood flow through the capillary bed that a relative anoxia of the capillary endothelium ensues. Because of this the permeability of the capillary endothelium is increased and there results an excessive exudation of fluid to the outside producing the edema. The edematous fluid has difficulty in getting back into the vascular system for two reasons, first, because the pump which is responsible for the movement of the lymph namely arteriolar pulsation is lost because of the arteriolar spasm and, second because spasm of the venules increases the pressure at the venule end of the capillary and inhibits absorption at this point. By overcoming the vasospasm by anesthetization of the sympathetic ganglia, the pain which is the result of ischemia is relieved and because of the prompt re-establishment of the normal circulation through the capillary bed the relative anoxia is overcome, the excessive exudation to the tissue spaces is prevented and by the re-establishment of the normal arteriolar pulsation the pump which is responsible for the movement of lymph is again brought into action and the edema quickly diminishes. Prompt subsidence of fever following novocain anesthetization of the lumbar sympathetic ganglia in phlegmasia alba dolens is probably due to the more rapid resolution of the inflammatory process in the vein wall resulting from better vascularization.

Because of the demonstration of these vasospastic phenomena associated with thrombophlebitis and their relief by anesthetization of the regional sympathetic ganglia, the treatment of phlegmasia alba dolens by sympathetic block is rational. Also the fact that these patients who would otherwise be incapacitated for weeks or months with persistent post phlebitic edema, recurrent erysipeloid infections and recurrent ulcerations are well within a few days time is additional proof of the adequacy and efficacy of blocking of the sympathetic ganglia in the treatment of phlegmasia alba dolens.

Fig. 2 Diagrammatic illustration of the effect of thrombophlebitis on the arterial bed and on the arterial pulsations. As shown in a, impulses originating in the thrombophlebitic segment, which are carried over the sympathetic nervous system to the arterial bed, produce a marked decrease in the size of the lumen of the vessel and a diminution in pulsation. b, Following anesthetization of these sympathetic ganglia, there is an interruption of these vasoconstrictor impulses, resulting in a return of the arterial lumen to normal and a re-establishment of normal pulsation.

The technique of lumbar sympathetic block is extremely simple and has been described adequately in previous reports (13-15, 16-18) (Fig 3). Although, theoretically, the employment of a single needle is sufficient it is our belief that if one uses multiple needles the block is much more likely to be successful because at best the injection is done blindly. With multiple needles the chances of striking the level in which the sympathetic chain is located are greatly increased. Because the patient with phlegmasia alba dolens is usually quite ill we prefer performing the sympathetic block with the patient in the lateral decubitus position. Points two finger breadths lateral to the spinous processes of the first, second, third and fourth lumbar ganglia are chosen. A cutaneous wheal is made. A long fine special needle $5\frac{1}{2}$ inches in length, is used. It is important to use a long needle because otherwise the anesthetic solution may be deposited into psoas muscle. The needle is introduced perpendicular to the skin until the point hits the transverse process. The transverse process serves as a landmark, because, whereas there may be considerable difference in the thicknesses of the subcutaneous fat and the sacrospinalis muscle of a large, muscular,

unnecessary procedure when better results can be obtained more safely and more simply by sympathetic block with procaine.

CONCLUSIONS

1 Because the symptoms and signs in true uncomplicated deep vein thrombophlebitis (phlegmasia alba dolens) are due to spasm of the arterioles of the involved extremity vasodilatation produced by section with procaine of the regional sympathetic ganglia is rational

2 Although ligation of the involved vein is imperative in phlebothrombosis and in suppurative thrombophlebitis in order to prevent emboli gaining entrance to the systemic circulation sympathetic block is sufficient in suppurative thrombophlebitis

3 By the prompt induction of vasodilatation the symptoms and signs in phlegmasia alba dolens are quickly alleviated and the postphlebitic sequelae are eliminated.

4 The use of multiple needles in performing sympathetic block greatly enhances the efficacy of the injection

ANTICOAGULANTS IN VENOUS THROMBOSIS AND THE PREVENTION OF PULMONARY EMBOLISM

GORDON MURRAY M.D. F.R.C.S. (Can) F.R.C.S. (Eng) Toronto, Canada

THE object of this paper is to discuss the effect of anticoagulants in the treatment of venous thrombosis, its prevention and the prevention and treatment of pulmonary embolism.

To approach this problem it seemed logical to consider the subject under the following headings:

1 Whether or not venous thrombosis is infective in origin. It is my impression as stated in a previous paper (7) that in only 5 per cent of the cases of venous thrombosis was infection a factor in production of the thrombus and even in these cases it is possible that the infection was a secondary invasion of a thrombus or clot which had formed from other sources. This evidence is based on the fact that in 28 cases of venous thrombosis which were operated upon cultures taken from the surrounding tissue from the wall of the vessel and from its lumen, showed no growth of organisms on ordinary cultures, aerobic cultures or on special media. The fact also that in the majority of cases if the extension of thrombosis can be prevented they clear up rapidly without further evidence of infection or suppuration lends further support to this view.

2 The beginning and extension of the thrombus. On clinical evidence, which was supported also by experimental evidence, I think it can be safely assumed that whatever may be the factors precipitating the thrombosis the lesion begins in a localized area and extends from such area as a propagating thrombus. This is well demonstrated in the cases in which the clinical signs and symptoms would indicate that the calf muscles may be the site of origin. From that point the progression of thrombosis with clinical symptoms

and signs extends through the adductor region to involve the femoral and presently the iliac vessels. In many cases at a later period the opposite leg is involved in what would appear to be a retrograde fashion. Also in the post mortem study of the vascular tree of the lungs in patients dying of pulmonary embolism, the primary embolus has been well demonstrated and on top of that has been built up a thrombus which is of more recent duration which extends more widely through the vascular tree until ultimately a fatal effect is produced—a fact which has been well demonstrated by Professor Boyd.

3 Ligation of vessels an exciting cause. There is evidence to suggest both clinically and experimentally that ligation of vessels, especially veins, may be the exciting cause for thrombosis, from which extension can occur. This is well known in operations involving dissection and removal of organs in the pelvic region where thrombosis with pulmonary embolism as a complication, is a fairly common occurrence. It has been demonstrated experimentally that if any major or minor vessel is divided tied sewn or allowed to become occluded by natural clotting and thrombosis that there is a process of thrombosis set up which extends proximally through that vessel for varying distances. In a vessel very carefully dealt with these thrombi may be only small fragments occurring in chinks in the vessel where it is gathered into a cone by ligation or where there are small irregularities from suture of the end of the vessel. However once this process is set in action it is purely a matter of accident just how far it will extend, if the other conditions favoring thrombosis are present. It is suggested, therefore that any form of surgery on the vascular tree, especially on the venous side, is not without some hazard as regards the initiation of this process of thrombosis with the unpredictable accident of pulmonary embolism as a complication.

It would seem obvious therefore, if thrombosis and clotting can be prevented or is not initiated that pulmonary embolism cannot occur leaving out for the moment, of course fat embolism. Much has been done in the way of clinical care of patients in an attempt to prevent early thrombosis in the vascular tree and from statistics in our own hospital the incidence of thrombosis and pulmonary embolism has been considerably reduced by care of the patient on the operating table and the avoidance of many of the conditions which are conducive to thrombosis. It may be stated emphatically that with the ultimate in view if by any means including giving anticoagulants, thrombosis in the venous tree could be prevented then the solution of pulmonary embolism and the late effects of thrombosis in vessels would be eliminated. It is obvious, of course that there are difficulties and objections to giving anticoagulants with this objective. For example there are groups of patients in whom the administration of an anticoagulant must be undertaken with great caution. In the postoperative group there may be the danger of initiating hemorrhage into the wound or in the operative field. However if the surgeon has in mind that an anticoagulant may be used, if the larger or medium sized vessels are adequately dealt with by ligatures, the danger of this is exceedingly small and this danger can be reduced to an absolute minimum by the careful administration of the anticoagulant and its proper control so that the clotting times and prothrombin times are kept within normal and reasonable limits as advocated in the early studies on these subjects. As well there is the added work and difficulty required in such treatment. However with the proper control and a fine understanding of the objective and the principles, these difficulties are not insuperable and in my experience they justify the end results.

I quite agree, for example in varicose veins with localized thrombosis in a varix, that ligation with continued activity of the patient offers simple and adequate relief of symptoms and almost certainly eliminates or prevents complications such as pulmonary embolism or extension to the main vascular tree. On the other hand with widespread thrombosis

through an uncertain area, it is more difficult to know just where ligation would be effective in loculating the area of thrombosis, to prevent further embolism. In my experience the question regarding the terminology of phlebotrombosis versus thrombophlebitis rests on the knowledge of the pathology of the course of events in thrombosis in the venous tree. As every operator has demonstrated, there may be thrombosis of vessels far in advance of the area suggested by clinical symptoms or physical findings of edema, tenderness, etc. As was explained in an earlier paper I believe these effects are as stated by Dr. Homans many years ago the result of the inflammatory reaction to a thrombus which has formed some hours or days previously. These inflammatory changes provide the patient with the cause of his symptoms, and the surgeon, with the findings of thrombosis. It is obvious, therefore, that the extent of the thrombus in the vascular tree is exceedingly difficult to delineate by physical examination. Also phlebography has given only partial satisfaction in delineating the uppermost extension of such a thrombus. As the surgeon has the objective in tying vessels, of loculating the process below his figure difficulties immediately arise. It is just here that anticoagulants enter into their best atmosphere. The effect throughout the vascular tree is universal and thrombosis, no matter where it is or where its extensions may proceed comes under the influence of anticoagulants. This is just as true in the question of further extension of thrombosis when embolism has occurred in the pulmonary artery as well as in the distal tree. It also has the advantages of having its effect in preventing intracardiac thrombosis (5). Especially is it true in the prevention of thrombosis in surgery either on the arteries (6) or on the veins themselves. I have found it of very great value in doing anastomoses as first done by Blalock, and have used it in 15 cases of the Tetralogy of Fallot. In none of these patients has there been thrombosis at the site of anastomosis as far as one can determine clinically and in none has there been cerebral thrombosis or other cerebral accidents neither has there been any evidence of pulmonary or peripheral embolism.

MURRAY ANTICOAGULANTS IN VENOUS THROMBOSIS

My evidence as regards the effect of anti-venous thrombosis and pulmonary embolism, is based on

1 Four hundred postoperative cases in which patients were treated with an anticoagulant with the objective of cutting down the incidence of thrombosis and consequently of pulmonary embolism. In this group no patient developed peripheral thrombosis and there were no cases of pulmonary embolism. Our experiment obviously includes too few cases to be of much significance except that the treatment was carried out in groups of cases in which from our hospital statistics, thrombosis and pulmonary embolism reached the highest figures recorded.

2 Three hundred and seventy-one cases of venous thrombosis in which treatment by anticoagulants was carried out with the objective of (a) preventing pulmonary embolism and (b) as treatment for the progressive thrombosis in the venous tree with a hope of relieving symptoms and of diminishing the ill effects so obvious and evident following venous thrombosis, such as persistent edema, varicose veins ulceration, etc. All these patients had typical symptoms and signs of venous thrombosis before treatment was started. The results of treatment were satisfactory in that none of the patients had pulmonary embolism. Moreover the late effects of the thrombosis were less severe than in a control group. There was less persisting edema, fewer ulcers in a 9 year period and fewer varicose veins during this time.

3 One hundred and forty nine cases of pulmonary embolism treated by anticoagulants. The cases were not selected and were obviously those which had survived the first embolism. In many of these the patients were in *extremis* at the time of beginning of treatment. Fifty two of these presented a state with which you are all familiar, the patient in alarming shock with no palpable pulse at the wrist, bordering on unconsciousness and with all the serious and dreadful effects of massive pulmonary embolism. From an analysis of histories of the hospital together with the postmortem findings, it has been demonstrated as shown on a previous paper that about 1 in 5 of all cases surviving the first pulmonary embolism is apt

to succumb to future embolisms or from the effect of propagating thrombosis increasing the effect of the original or subsequent embolism.

This group of patients with pulmonary embolisms here reported are those over whom I had control during treatment. In these I had information that the treatment was adequate and that the necessary effect on the clotting time or on the prothrombin time was obtained. I saw a fairly large number of similar cases in consultation with other doctors who undertook the treatment of the patients and for that reason these are not included in this report. I have learned subsequently of 3 deaths in this group treated by other doctors. In those in whom I had control of the treatment and knew that the adequate effects on the clotting and prothrombin times had been obtained there were no deaths from embolism in 149 cases. Four of these following the beginning of treatment, had further embolisms which were obviously small in nature because they produced only slight effects on the patient.

It is very impressive to see the effect on a patient with massive pulmonary embolism or with extensive thrombophlebitis or both the improvement that takes place in a matter of very few hours is striking once the effect on clotting time has been obtained. The pulmonary distress with dyspnea, pain etc. together with the embarrassment of heart action are diminished progressively in relatively short time so that within a few hours there is a measurable change and within 24 to 36 hours the alarming symptoms have largely disappeared. It may take several more days before there is complete relief of all symptoms.

During the course of such treatment, it has frequently been observed that there was no obvious swelling or edema of extremities at the time of the massive embolism. However, during the course of treatment one leg has enlarged and showed "quite marked edema and on some occasions at the same time, or within a few days the other leg has gone through similar changes. It is my impression from a study of the pathology that this is no indication of ineffectiveness of the treatment by anticoagulants. I believe that at the time of the embolism there obviously was a massive thrombus at some site in the venous tree

which was so insecurely attached that it broke off and floated as an embolus. However at this stage the inflammatory reaction in the wall of the vein and surrounding tissue had not reached the point where it had produced clinical symptoms. Even under the treatment by the anticoagulant, which can only prevent the further extension of thrombosis, the remaining thrombi have excited the inflammatory reaction which has gone through the changes necessary to healing of the lesion.

To accomplish this effect, in the presence of thrombosis or embolism, it is absolutely essential that the original principles of application of anticoagulants be followed. First, if heparin is administered it must be carried to the point where the clotting time in the patient is kept at or about 15 minutes. It is of no use whatever to give heparin blindly and not know that the effect is being obtained. Because the effect of heparin is so evanescent and because the dose is variable for the individual, the only safe way to be sure of this effect is to do clotting times at short intervals. The next principle is to give the anticoagulant until the healing process in the area of existing thrombosis has reached the stage where no further thrombosis will take place. From our experience in the average patient who is able to get out of bed the patient is kept at rest for 3 or 4 days under the treatment. Following this exercise is encouraged and within 6 or 7 days of the beginning of treatment the patient is urged to be out of bed and exercising actively. When the patient can go through this with some energy probably on the seventh, eighth, or ninth day the heparin treatment is discontinued. If however the patient has some lesion or operation which necessitates staying in bed then the treatment is continued for longer periods up to 3 and occasionally 4 weeks, in such cases as spinal fusion where the patient has not been allowed to be out of bed. It was demonstrated experimentally that a thrombus placed in a vessel is endothelialized well within this period of time and probably that is the best protection against further extension provided the remaining physiology of the patient has reached normal.

Dicoumarol has many advantages over heparin in the way of expense and the ease of

administration. However in my experience it is not quite as effective as is heparin, in preventing extension of thrombosis. It can be used however as an important adjunct. When the patient has begun treatment with heparin for 2 or 3 days, the dicoumarol can be added as a supplement and the patient encouraged to be ambulatory under this treatment with greater ease.

I have not used any of the thrombolytic substances in an attempt to dissolve clots. A few patients were treated with sodium tetrathionate, but not enough to determine its value. In those treated the effect seemed to be excellent.

Dr. Allen at the Mayo clinic has reported (1) a large group in which anticoagulants were administered with excellent effects. Also the group in Scandinavia, namely Zilliacus, Hedenius, Jorpes have reported large groups treated with anticoagulants with satisfaction.

One advantage of using anticoagulants also is that in a patient who is on the verge of collapse the treatment involves very little disturbance and in my experience the effect has been dramatic. This may have advantages over operative procedures where either injection or operation involves the undertaking of more active and energetic measures for which a patient may be in very poor condition.

CONCLUSIONS

1. Intravascular thrombosis and clotting can be prevented by anticoagulants, heparin, and dicoumarol.

2. If thrombosis and clotting have occurred, anticoagulants in appropriate doses will prevent further extension of the process.

3. If a patient is adequately treated with anticoagulants following pulmonary embolism, the chances of survival are excellent.

CARCINOMA OF THE COLON

A Statistical Analysis

WILLIAM J VYNALEK, MD FACS Berwyn Illinois, LESLIE L SAYLOR MD Topeka Kansas, and ROBERT SCHREK MD., Hines, Illinois

THIS paper represents a study of all the patients with carcinoma of the colon not including the rectum and sigmoid admitted to the Veterans Administration Hospital, Hines Illinois from 1931 to 1945 inclusive. A similar review is being made by other workers at this hospital on carcinoma of the rectum and sigmoid. During this 15 year period this institution has been the tumor center for all Veterans hospitals of the Midwest and a large volume of material and records is available for study and analysis.

The purpose of this paper is to add to the growing number of cases being reported so that totals of statistical significance may be amassed to analyze the material and to attempt to draw pertinent conclusions. Each record of admission was studied with reference to age, duration of symptoms common complaints, important physical and laboratory findings, surgery operative and numbers and of irradiation pathology and numbers and length of survivals. It is a difficult task to take a maze of data and present conclusions in a simple readable form. Follow up records are practically one hundred per cent complete because of government pension regulations and the persistent efforts of a specially created tumor registry section.

There were 131 279 admissions of all types during this 15 year period and 16 097 (primary admissions) of these were patients with carcinoma. In 1330 of these admissions, the primary lesions were in the large bowel colon, and rectum included. In Figure 1 are shown

the sites of predilection. Many writers have repeatedly stressed that two-thirds of all carcinomas of the large bowel involve the rectum and rectosigmoid and can be felt by the finger of the careful examiner. These and certain others in the lower sigmoid likely to be missed by barium enema can be seen through the proctosigmoidoscope and specimens obtained for biopsy study. Points of flexure and the cecum have a moderately high incidence considering their short span. They presumably receive the maximum mechanical and chemical trauma which might play a rôle in carcinoma of the colon.

The close similarity in the frequency of the sites of involvement in our patients with those reported by others is shown in Table I and is of biological significance.

This study concerns itself primarily with the 486 patients who had involvement above the rectosigmoid. The histories were divided into two groups before and after January 1 1941. This division is convenient because it gives data as to 5 year cures and because of the adoption of improved methods in anesthesia and in preoperative and postoperative care in the latter period. These included better colon decompression, the various sulfa drugs later penicillin, and liberal use of blood transfusions and continuous gastric suction. Their salubrious effect on surgical mortality and morbidity seems clinically and statistically to have ushered in a new era in colon surgery.

In Figure 2 are given percentages of resectability for the entire period. In the term resectable are included only those cases in which a cure can reasonably be anticipated following removal of all gross carcinomatous tissue. It includes those in which adjacent resectable organs and lymph glands are involved. A non resectable lesion implies distant metastatic spread to liver lung bone brain or non removable lymph glands. In the nonresectable

These included better colon decompression the various sulfa drugs later penicillin and liberal use of blood transfusions and continuous gastric suction. Their salutary effect on surgical mortality and morbidity seems clinically and statistically to have ushered in a new era in colon surgery.

In Figure 2 are given percentages of resectability for the entire period. In the term resectable are included only those cases in which a cure can reasonably be anticipated following removal of all gross carcinomatous tissue. It includes those in which adjacent resectable organs and lymph glands are involved. A non resectable lesion implies distant metastatic spread to liver lung bone, brain or non removable lymph glands. In the nonresectable

Fig. 5. Number of one and multistaged resections of carcinoma of colon and operative mortality

Resections in all segments of the colon reflects this statistically significant lowering of the operating mortality, but the right half of the colon is especially favored. Pack and Livingston state that an operative mortality of 10 to 15 per cent can be expected if there is no selection of cases. However with some clinics reporting a surgical mortality of less than 4 per cent, there is ample room for improvement in our results.

Figure 4 shows the operative mortality by years. The change began gradually during 1940 and is striking thereafter. It cannot be attributed to improvement of surgical technique.

In Figure 5 it is noted that resections were done in one stage in only 25 per cent of the 1931-1940 cases, but in 51.6 per cent in the 1941-1945 group. Although the mortality in single and multiple stage procedures in the 1941-1945 group is about the same the increased number of one stage procedures possible is of great significance since it reduced the period of hospitalization from 2 months or more to 3 weeks or less, and it added to the comfort of the patient. With the present day shortage of hospital beds, the successful shift to one stage procedures is of tremendous value and is in line with the general trend throughout the nation. The good reason for the early tendency toward multiple stage procedures in the 1931-1940 period is indicated by the mortality rate of 56.2 per cent for the

one stage, contrasted with 29.1 per cent for the other.

In Figure 6 the survivals of 5 to 15 years following resections in the 1931-1940 group are shown. Of the 281 colon cases admitted in this first period, omitting those resected or explored elsewhere and sent here for routine x ray therapy or terminal care 193 candidates were left for possible resection. In 64 resection was accomplished and 21 or 32.8 per cent of the resectables are alive today. Of the resectables who survived the operation in that first period when the mortality rate was so high, 51.2 per cent are alive over 5 years. With the lowered mortality rate of the second period, it is to be expected that approximately 50 per cent of the resectables can be offered a 5 year cure and this is the approximate figure of the most successful tumor clinics. Post operative prognosis is best in right side lesions.

In 41 cases resection was done elsewhere in the 1931-40 group and the patients were sent to Hines for routine x ray therapy or terminal care. Of these 13 or 32 per cent, were alive 5 to 15 years later. Improvement in the surgical mortality rate is gradually reaching a point where for further progress the only means of obtaining more cures is to make earlier diagnoses to increase the percentage of resectables. Herein lies considerable room for improvement.

Figure 7 presents a comparison of the survival of patients following curative resection

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE II.—DATA FOR THE CONSTRUCTION OF 1931-1940 AND 1941-1945 SURVIVAL CURVES

	No. of patients with curative resections	month		year		year		3 year		4 year		5 year

tumor in a higher percentage of cases than formerly

SYMPTOMS

These patients were all veterans the majority from World War I. They were all in most cases the carcinomas occurred between the ages of 45 and 50 years. Symptoms were present from sudden onset to several years before a diagnosis was made. An average of 6 symptoms and hospitalization in those found to 10 months passed between the onset of resectable the average duration was 6.3 months, in the nonresectable group 9.7 months. Lahey states that at that clinic the interval for all cases has been 9 months with no appreciable improvement in recent years.

Fig. 8. Survival curves of patients surviving one month or more after curative resections for carcinoma of the colon.

There are no pathognomonic symptoms of cancer of the large bowel but sufficient warning is given to justify study which will usually lead to an accurate diagnosis. Unfortunately many patients still undergo trial medical treatment, hemorrhoidectomies, or appendectomies before diagnostic studies are instituted. The most common and suspicious complaints are enumerated as follows (Fig 9)

1. *Abdominal distress* frequently more marked in the region involved, though often enough to cause confusion, obstruction of the left colon may cause most distress in the dilated right bowel. The character of the distress varies and seems to be directly related to the degree of obstruction. It may be dull, but as the lesion tends to be located more toward the left with its semisolid stool and a tendency toward the formation of annular constricting lesions, obstructive pain occurs with colic, nausea, and vomiting. Discomfort is usually aggravated by eating and relieved by bowel movements especially if the stools are kept liquefied by cathartics. In 7 per cent of left colon lesions an acute obstruction ushered in the first sign of trouble. Fourteen per cent of splenic flexure lesions began in this manner. Gordon Heyd states that 5 per cent of sigmoid tumors begin with acute obstruction. Carcinoma of the cecum is frequently diagnosed clinically as an appendicitis, and appendectomies had been performed on 19 of the cecal cases just before admission to this hospital. Usually the surgeon recognized that there was cecal pathology present at operation.

VYNÁLEK ET AL. CARCINOMA OF COLON

SYMPTOMS

FINDINGS

Fig 9. Symptoms and signs in patients with carcinoma of the colon.

2 *Change in bowel habits* is an important and frequent symptom elicited only by a carefully taken history. Constipation is common regardless of the location of the lesion but more pronounced and annoying in left half colon pathology. It frequently alternates with diarrhea often because the patient does himself with cathartics at regular intervals. However diarrhea instead of constipation may be the patient's complaint.

3 *Mass in the abdomen* was mentioned by the patient himself in 25 per cent of the cases with involvement of the cecum or ascending colon. 6 per cent of the sigmoid group and rarely by others. Gordon Heyd states that 10 per cent of the people with carcinoma of the cecum discover a lump in the right side before consulting a physician.

4 *Weight loss*, contrary to the usual belief is often an early sign and is present in practically all. It may occur rapidly but ordinarily appears slowly. From 16 to 75 pounds loss of weight was common but in some patients with a violent obstructive onset there had been no previous loss.

5 *Blood in the stools* is mentioned in the histories of 33 per cent of patients with lesions in the left half of the bowel with their tendency toward the appearance of conspicuous red

blood but only 8 per cent of those with right colon involvement mentioned melena. Unfortunately the record often fails to note any questioning on this important point.

6 *Other complaints* Anemia, of an intense degree is always stressed in the literature in connection with cancer of the cecum. It is spectacular and impressive when it occurs but was uncommon in this series. The red count was usually normal even in the cecal cases until late in the disease when curative surgery was impossible. Only 13 of the 102 cecal cases had a red blood count below 3,000,000. In only 2 patients anemia and weakness were the main complaints. Of the 53 ascending colon lesions 6 had a red blood count below 3,000,000.

Indigestion, weakness, nausea, vomiting, anorexia and fever were frequently mentioned.

FINDINGS

1 *A palpable mass* was noted at the initial examination by the Veterans Hospital physician in 81 of the 102 cecal cases, 14 of the 53 ascending colons, 20 of the 27 hepatic flexures, 26 of the 55 transverse colons, 11 of the 27 splenic flexures, 22 of the 49 descending colons, 87 of the 173 sigmoids averaging 69 per cent.

This is a rather high figure compared to that of others who mention 10 per cent to 33 $\frac{1}{3}$ per cent as having palpable masses on the right, seldom on the left, and again indicates that many of our patients arrive late. However the palpation of a tumor does not necessarily indicate a hopeless process.

2. *Tenderness* of varying degree is frequently present at the site of involvement.

3. *Occult blood* in the stool was surprisingly seldom searched for but usually positive if the tests were ordered.

4. *Barium enema x ray studies* practically always revealed a suspicion-arousing defect which was usually properly interpreted. The segment where pathology was most often overlooked was the sigmoid in which x ray studies missed the lesion in 9 per cent of these cases.

5. *Proctoscopy* following digital rectal examination is without a peer in lesions up to 23 centimeters from the anus.

PATHOLOGY

Pathology was proved by microscopic studies in 68 per cent of the series. Autopsies were secured in 145 (37%) of the 390 known dead.

Adenocarcinoma or a colloid modification was the usual finding occasionally an undifferentiated carcinoma. In lesions thought by the operator to be nonresectable a large firm mesenteric gland was frequently taken for biopsy and the pathologist's report was usually negative for carcinoma. This implies that neither surgeon nor pathologist is able to diagnose cancer of the lymph nodes grossly or to differentiate from inflammation. A frozen section at operation might prevent classifying a condition as inoperable.

Operative deaths were usually due to peritonitis, embolism, pneumonia, shock and myocardial damage. One cecal case succumbed to gangrene of the terminal small bowel after resection due to thrombosis of the ileocolic artery.

Multiple polyposis was noted by the pathologist, surgeon proctologist or roentgenologist in 11 (2.2%) of the 486 patients of this study. The primary carcinoma in these cases was located as follows: cecum, 2; transverse colon, 3; splenic flexure, 1 (this patient also

had a concomitant cancer of the hepatic flexure) descending colon, 4; and sigmoid, 1.

In 3 instances in this entire series multiple cancers of the large bowel were found. Perforations into small bowel and stomach were noted in a few instances. Bladder attachment, but not perforation, was occasionally mentioned. Hydronephrosis secondary to a cinomatous obstruction of the ureter seldom occurred. Abscesses often complicated the picture, and required preliminary drainage.

IRRADIATION

Irradiation was used frequently as a "palliative" measure in the earlier years with no outstanding improvements. Doses of a total of 100 to 6000 roentgens are reported, but deep therapy is no longer considered of much value for lesions above the rectosigmoid. It was felt that x ray therapy following drainage of abscesses definitely shortened the period of waiting preparatory to radical surgery.

AVERAGE SPAN OF LIFE

In the inoperable cases death occurred 11 months after onset of symptoms, a speed which suggests a vicious process. In those having a simple exploration death occurred 6 months after operation and 16 months after onset of symptoms. Those who underwent palliative resections lived 17 months after operation. As had been shown previously the majority who died after attempted curative resections did so in the first and second years but some died of recurrence as late as 6 years following operation.

SUMMARY

A survey has been made of the 486 cases of carcinoma of the colon seen at Hines Veterans Hospital, Hines, Illinois, during the past 15 years. The sites of predilection are almost identical with large groups reported elsewhere. The resectability rate of 35.6 per cent is low. The drop in the mortality rate following surgery from 35.9 to 9.7 per cent in recent years is encouraging. The 5 year survival rate approaches the 50 per cent figure of the larger clinics. More one stage procedures are being done in recent years. A review of pertinent data is given.

ANTICOAGULANT THERAPY IN THROMBOSIS

J ERIK JORPES, M.D. Stockholm Sweden

THE specific treatment of thrombosis seems to demand the use of anticoagulants. Thrombosis arises through intravascular clotting of the blood in a pulmonary embolism is simply a fibrin clot detached from the walls of a peripheral vessel. In the past considerable attention has been paid by such men as Morawitz, Howell and others to the possibility of using anticoagulants to prevent thrombosis. Although heparin the natural anticoagulant of the body itself was discovered in 1916 by MacLean¹ working with Howell, very little benefit came of it during the next 20 years. As early as 1933 Charles and Scott of Toronto elaborated a method for large scale extraction of heparin from liver and lungs and the chemical nature of the drug was elucidated 2 years later (Jorpes). Thanks to these efforts heparin has been made available. Crafoord of Sweden and Murray of Toronto were the two surgeons first to use heparin clinically

PROPHYLACTIC USE OF HEPARIN

During the years 1935 to 1940 it was clearly demonstrated that postoperative thrombosis and pulmonary embolism could be prevented if heparin were administered in adequate doses over an adequate length of time. In Sweden Crafoord Wetterdal and Lessner heparinized about 800 patients postoperative-

ly and in Canada Murray reported the results in treating 400 patients in the same way. Although a high incidence of thrombosis was expected 2 or even 4 per cent, practically no complications occurred. Two hundred fifty milligrams of heparin a day was found to be an adequate dosage. In the Swedish series heparin was given to 657 patients, the treatment being started on the second or third day after operation or childbirth.

Similar successful results have been reported from the use of dicoumarol Barker and his co-workers at the Mayo Clinic administered dicoumarol postoperatively to 1,000 patients and in Sweden Bruzelius treated 1,600 patients in the same way. In each series there was a marked decrease in the number of thrombotic complications.

Because of the expense involved and the risk of hemorrhage there will however, be no question about giving heparin or dicoumarol to every patient after operations or childbirth.

Prophylactic treatment with anticoagulants must be restricted to cases in which the risk of a thrombosis occurring is considerable e.g. after parturition in a patient who has had thrombosis during pregnancy or after operations on patients who have suffered from earlier repeated thromboembolic attacks after operation childbirth, or miscarriage. In such instances heparin has frequently been used in Swedish hospitals, starting with 50+50+50+100 milligrams of heparin a day at 8 12 16 and 20 hours from the second or third day onward for 5 to 8 days, until the patient is able to get up and can move about freely.

only were quite without discomfort. The 13 remaining had symptoms in the leg. All suffered from swelling of the lower part of the leg in most instances moderate to severe. Five had in addition swelling of the thigh 3 had severe pain and a feeling of heaviness in the leg.

At Bauer's clinic, where all cases except those with thrombosis diagnosed before their arrival at the hospital received early heparin treatment, the process did not progress beyond the calf in 80 per cent of the cases and it stayed in the calf in all cases where heparin was given before a phlegmasia had developed. From Zilliacus's data on conservatively treated cases, it appeared that thrombosis spread to the thigh in 80 per cent of the cases. In his series of cases treated with anticoagulants—the cases presumably were not treated in the most efficient manner as far as early diagnosis and therapy were concerned—the process spread to the thigh in spite of the specific therapy in 55 per cent of the cases.

It was noted by Zilliacus that when the thrombosis had extended to the thigh there was little difference between the conservatively treated cases and those treated with heparin. Swelling of the calf with discoloration induration with large varicose veins were present in most of the cases of both groups. Ulcus cruris occurred in 11 of 154 cases treated with heparin and submitted to follow-up examination. The result in this group was the same as that among the conservatively treated cases. An important difference, however as compared with the conservatively treated cases,

was that bilateral symptoms occurred only in 3 cases instead of in 33 per cent as found among the conservatively treated cases.

The sequelae in the patients with thrombosis of the calf who were treated with heparin were generally mild. Of 130 such cases 66 were completely free from symptoms, while the remaining patients showed only swelling of the calf after exertion. Only 1 patient in the group suffered from ulcer of the leg.

The specific therapy had, thus, in cases in which the thrombosis remained localized to the calf permanently saved the patients from a chronic, painful, more or less severe, disablement.

THE TECHNIQUE OF ADMINISTERING HEPARIN

In most of the Swedish clinics heparin administration is started as follows: 350 to 450 milligrams a day are divided into four intravenous injections which are given at 8:00 a.m., 12:00 m., 4:00 p.m. and 8:00 p.m. or 10:00 p.m. In amounts of 125, 100, 100 and 125 milligrams. On the third day the dose is lowered, e.g. to 300 to 350 milligrams. In case dicoumarol is given on the first day heparin is omitted as soon as an appropriate prothrombin level is reached. The same scheme is followed even in case of an acute pulmonary embolism. The use of dicoumarol alone is not permitted because it has repeatedly been observed that thrombosis in the calf proceeds to the thigh in spite of dicoumarol treatment. In fact heparin treatment has aborted the disease before the full action of dicoumarol

JORPES ANTICOAGULANT THERAPY IN THROMBOSIS

has evolved. Patients are consistently asked to move about in the bed as much as possible even on the second day and early ambulation is routine. Thus the average time in bed in Jauer's series was 4.6 days and in the other Scandinavian series 1 week to 10 days instead of 5 to 6 weeks as found in the series of patients treated conservatively.

Treatment now varies under different conditions. In small hospitals where no prothrombin analyses can be made only heparin is used. The time of coagulation of the blood is as a rule not determined. There seems to be a very small risk in using heparin without blood analyses. As to the use of heparin the contraindications seem to be very few. The risk of hemorrhages occurring is minimal. Hemorrhage is to be considered in the prophylactic treatment of postoperative cases but it has proved to be very insignificant in the ordinary treatment of leg thrombosis and pulmonary embolism.

OTHER THERAPEUTIC MEASURES

The question arises whether similar results as those reported here also could be obtained by other means, such as through active movements and early getting up from bed, sympathetic block causing vasodilatation in the leg and surgical ligation of the larger veins.

It is evident that exercises under medical supervision and the early getting up of patients

can reduce the incidence of thromboembolism. The incidence of thrombosis can be reduced to about 0.6 per cent in surgical clinics as is evident from Table IV.

Even in the Scandinavian series the mortality rate in thrombosis is still about 20 per cent, the same figure as that found at the beginning of this century in the surgical clinics of Germany and Austria as well as at the Mayo Clinic in this country during recent years. Consequently, there is a need for specific therapy.

The principles to be applied will at least partly depend upon the prevailing conditions. Venous ligation has in larger surgical units in this country given extraordinarily good results. In clinics where the prothrombin level of the blood can be adequately followed, dicoumarol has been used either alone or in conjunction with heparin. In all smaller hospital units, like that of Baner in Sweden, heparin treatment can be applied successfully. It is in fact to be resorted to in every case of early peripheral leg thrombosis and in acute pulmonary embolism.

The relative value of the different methods for the treatment of peripheral leg thrombosis or pulmonary embolism will of course become the subject of closer study during the next 5 to 10 years. At present we can confine ourselves to the statement that physiology and biochemistry have given us specific means which are highly effective in the treatment of thrombosis.

THE TREATMENT OF CHRONIC NONTUBERCULOUS PULMONARY ABSCESES BY HIGH VACUUM SUCTION DRAINAGE

HARRY E. NELSON M.D. Dallas, Texas

DURING the past few years there has been progressive improvement in the management of chronic pulmonary abscesses. Lobectomy or occasional external drainage is now being employed with excellent results. It is felt, however, that in some well selected cases equally good results might be obtained by simpler means.

Often simple external drainage will fail and lobectomy despite the excellent results, remains a formidable procedure which may result in the loss of some functional pulmonary tissue which demands much of the time and energy of a skilled thoracic surgeon, an experienced anesthesiologist, and a trained surgical team as well as the services of a blood bank. No time need be spent, therefore, in advancing the desirability of a simpler method of treatment.

The purpose of this brief communication is to describe what may be such a method of treatment for certain carefully selected cases of chronic pulmonary abscess. To date, it has been employed in only 10 cases, but the results in all in which the method has had a fair trial have been so good that it seems justifiable to place the small series on record in the hope that other surgeons may be encouraged to test the method and that a group large enough to be of statistical significance may be accumulated for analysis within a reasonably brief period of time.

The method proposed is an application of the continuous high vacuum suction drainage described by Neville in 1939 for the management of chronic empyema thoracis. He was confronted with a patient slowly wasting away with chronic empyema of 2½ years duration.

From the Division of Surgery, Southwestern Medical College. Presented in the forum on Fundamental Surgical Problems, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Within 4 weeks after thoracostomy and the institution of high vacuum suction drainage, the previously extensive empyema cavity had been reduced to a straight tract the size of the drainage tube, and within 7 months the patient had returned to work and was apparently completely well.

When this method came to my attention shortly after it had been described, it struck me that it might be useful in certain types of pulmonary abscess which in chronicity and other respects could be considered analogous to chronic empyema. The validity of the method as applied to chronic pulmonary abscesses seemed enhanced by a careful study of pulmonary lobes resected for this cause. In some of these cases the conclusion seemed warranted that a cure might have been obtained by simpler means, with greater economy of time and personnel, with conservation of pulmonary tissue, and with less risk to the patient.

The term chronic in this connection is used to designate that type of pulmonary abscess which has existed sufficiently long to show roentgenologically a definite fibrous tissue capsule. Not all observers, of course, would agree with this definition but as the basis of selection of cases for high vacuum suction drainage, it is an entirely adequate point of departure. If the zone of surrounding fibroplastic tissue is slight as in the type of abscess which in some quarters might be termed subacute or even acute, the abscess is given the opportunity to heal spontaneously or simple external drainage is employed. If on the other hand a considerable degree of lobar fibrosis and bronchiectasis is present, lobectomy is regarded as indicated.

The selection of cases for this method of treatment rests on still other criteria. The abscess must be single. It must be peripherally

Fig. 1. Roentgenogram taken prior to operation revealing a spherical mass peripherally placed in the lower part of the upper lobe and in contact with the parietal pleura.

Fig. 2. Lateral projection corresponding to Figure 1 showing the lesion to occupy the posterior part of the upper lobe.

located. A pleural bridge must exist, so that satisfactory external drainage can be instituted without traversing the pleural space. If malignancy is a possibility and if the usual diagnostic measures do not absolutely exclude it, exploratory thoracotomy and biopsy must be carried out. Finally the lesion must be observed sufficiently long to make certain that the cavity is not decreasing in size spontaneously or under conservative methods of treatment. If these various criteria are met, the case is regarded as suitable for high vacuum suction drainage.

The operation is preferably done under intercostal nerve block. If preliminary aspiration reveals the existence of an adequate pleural bridge the lesion is approached directly. If there is doubt regarding or definite evidence against the existence of such a bridge, exploratory thoracotomy is carried out by way of a small strategically placed incision and the site of the skin incision for drainage is determined by the location of the pleural bridge.

If no bridge is found the method of treatment contemplated must be discarded in favor of lobectomy.

The abscess cavity is entered after resection of a small segment of overlying rib and a drainage tube of appropriate size is inserted and made air tight by the use of flanges and sponges. Patent bronchial openings in the walls of the cavity are fulgurated but if this procedure be necessary suction drainage is not instituted until they have closed.

Neville described the machine which he had devised for his patient, but in hospitals equipped with built in suction systems no special machines are necessary. The suction apparatus is set at between 5 and 10 inches of mercury and the level is decreased only if the patient complains of a sense of severe pulling in the chest or if hemorrhage of serious degree occurs. The routine described by Neville is carried out with minor modifications. Thoracoscopic inspections of the cavity are made at weekly intervals and the measurements are

Fig. 3. Roentgenogram taken after operation shows the drainage tube passing through the resected segment of the fifth rib and the decrease in density of the lesion following suction therapy. The abscess cavity previously invisible is now quite apparent.

Fig. 4. At the time this film was taken the tube had been removed although the film indicates that a cavity may still be present. This is due to the peculiar arrangement of the fibrous tissue remaining in the upper lobe. The cavity has been observed fluoroscopically to flatten out against the parietal pleura and become obliterated. This patient has been asymptomatic for over 2 years and bronchograms reveal no abnormalities.

recorded at the same time for comparative purposes.

As soon as the patient is sufficiently improved to leave the hospital, he is instructed in the use of a small suction machine (available on rental from a commercial firm) which is similar to the standard tonsillectomy suction machine but is mechanically superior. It is capable of maintaining high vacuum suction for prolonged periods, with only brief intervals of nonoperation for the purpose of cooling the motor. The patient returns at intervals as necessary for observation until the abscess cavity is obliterated.

In every case in which a patient was treated by this method the clinical course has been the same. Following closure of the fulgurated bronchial orifices, if fulguration has been necessary and the institution of high vacuum suction drainage the size of the abscess cavity decreases rapidly and striking changes occur in the granulation tissue lining it. Previously

pale and edematous, it rapidly assumes a healthy appearance and many new blood vessels are observed. The sites of the bronchial openings gradually disappear and the medial wall of the cavity approaches, and finally flattens out against, the parietal pleura. This important development in the healing process is hindered when the cavity is packed but is encouraged by the suction method of treatment.

In about half of these cases suction was discontinued for periods of as long as 2 weeks, as a control measure. Invariably the diminution in the size of the cavity previously progressive, was halted and was not resumed until suction was reconstituted.

The 10 patients in this series ranged in age from 20 to 65 years, every intervening decade being represented. The duration of illness prior to treatment had ranged from 3 to 12 months. Suction drainage was necessary for

an average of 3 weeks. In no instance in the series did it fail to bring about prompt decrease in the size of the cavity eventual complete obliteration and corresponding improvement in the condition of the patient. No untoward results of any kind have been connected with its use. The earliest of the cases has been followed for a 2 year period and all other patients have been followed for at least a year. During the period of observation there has been no recurrence in any case though, because of the short time interval since treatment, the possibility of recurrence cannot be entirely discounted. Roentgenologic exami-

nation after obliteration of the abscess cavity has revealed in all cases persistence of shadows indicative of residual fibrosis.

Although the present series, as stated, consists of only 10 cases, the results secured seem to justify this preliminary report, chiefly because it is hoped that others will test high vacuum suction drainage in chronic nontuberculous pulmonary abscess and will report their results.

RATE OF GAIN IN STRENGTH IN SUTURED ABDOMINAL WALL WOUNDS

JOHN FAST, M.D. CARLETON NELSON M.D. and CLARENCE DENNIS M.D.,
Minneapolis, Minnesota

IN recent years a great deal of attention has been given to early ambulation following laparotomy. The strength of a wound immediately following the placement of sutures depends primarily on the total number of sutures which have been placed and upon the ability of the tissues to hold the sutures as well as the tensile strength of the suture material employed and the manner of placement of those sutures. A review of the literature on wound healing yields very little reference to the rate of strength gain across incisions through the rectus muscle and fascia following approximation of the muscle and fascia with interrupted silk sutures. In the present study our objective is the determination of the amount of healing at different periods of time by measuring the tensile strength of the healing wound with non-absorbable sutures remaining in place.

According to Howes and Harvey the rate of strength gain in a healing wound resembles the curve of growth in general (4). There are 2 periods in the strength gain of a healing wound, the first, the so-called 'latent period' (2) lasts from 3 to 5 days. In the second period of the curve of normal healing strength increases rapidly and this phase continues until the wound is completely healed. Microscopically this period is associated with the process of fibroplasia (5).

METHODS

For the purpose of this experiment commercially raised healthy white rabbits were employed. These rabbits were maintained throughout the experiment, on a stock rabbit diet consisting of rabbit pellets and water. They were kept on this diet both before and after operation, and no attempt was made to add or subtract any dietary factor which would enhance or hinder the process of wound healing. Also no attempt was made to choose a uniform size, weight, or sex. Both medium and large healthy rabbits were employed.

From the Department of Surgery, University of Minnesota. Supported by a Research Grant from the Graduate School of the University of Minnesota.

Presented in the forum on Fundamental Surgical Problems before The Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

Fig. Tensiometer employed for determination of strength of tissues. The strip of tissue to be tested is gripped in two forceps which remain perpendicular to the line of tension. The tension is slowly increased by turning a large spool connected by a wire to one of the forceps on the

tissue. The other forceps is attached by wire to the spring. A rider point is moved over the calibrations on the guide bar by the stretching of the spring, and marks the point of maximum tension. Control tissues regularly ruptured mid way between the clamps.

The rabbits were anesthetized by the injection of a necessary amount of aqueous sodium pentobarbital into the marginal vein of the ear. Roughly 35 milligrams of the drug were used per kilogram of weight. The hair was removed from the abdomen with barium sulfide and the skin washed thoroughly with water to remove all traces of the chemical. No marked skin reactions were observed from the use of the barium sulfide as a depilatory. Skin sterilization was obtained by the use of Novak's solution (6) and sterilization was maintained by the use of sterile towels as drapes around the operative field. Rubber gloves were not worn during the operation but operations were preceded by a 10 minute scrub with soap and water followed by rinsing in aqueous zephiran solution. Surgical instruments, heat sterilized prior to the first operation of the day were kept in a solution of aqueous zephiran 1:1000 between cases. The No 000 and No 0000 black silk (Deknatel) used for closure was autoclaved at 250 degrees for 10 minutes. All suture material was new and none of it was autoclaved more than once.

A midline skin incision roughly 14 centimeters long was made beginning at a point just below the xiphoid process and carried down to the lower midabdomen. This incision exposed the linea alba. At this point the superficial fascia was separated either to the right or to the left of the midline and one an-

terior rectus sheath was exposed. An 11 centimeter incision was then made through the midanterior rectus sheath, rectus muscle, posterior rectus sheath, and peritoneum, usually about 1 centimeter from the midline.

The closure of the rectus incision was made by interrupted sutures. No 000 silk was used in some rabbits, and No 0000 silk was used in others. The anterior rectus sheath, rectus muscle, posterior rectus sheath and peritoneum were all included in interrupted through-and-through stitches placed at regular 5 millimeter intervals. The bite included 2 millimeters of tissue on each side, and knots were tied with one square knot just tight enough for apposition without blanching. The skin was closed by means of a continuous suture of black cotton.

The rabbits were studied at varying times during their periods of wound healing. Some were sacrificed immediately and their wounds measured for tensile strength, others were sacrificed at 24 hours, 48 hours, 72 hours, 5, 7, 9, 11, 15, 21 days and 6 weeks. No fewer than 6 rabbits were used for any single period's determinations except 9 days, and as many as 18 rabbits were used for some. In all, a total of 128 rabbits was used in this series, roughly 20 to 24 determinations were made on each rabbit, a total of roughly 2400 separate observations in all.

The rabbits were killed by the intravenous administration of 10 to 15 cubic centimeters

TABLE I — TENSILE STRENGTH OF SILK SUTURED ABDOMINAL WOUNDS IN RABBITS

Ratio of strength of wound to strength of previously undisturbed side			
Time interval	No. of rabbits	Mean ratio per cent	Standard deviation
0	—	0	0
1 day	6	30.9	—
2 days	6	—	1.0
3 days	7	—	3.5
5 days	6	1	—
7 days	—	14.9	—
9 days	—	23	9
13 days	4	3.5	3.3
15 days	7	5.8	—
17 days	4	7	6
21 days	5	8	1

N.B. The ratio of tensile strength of the control sides varied from 11 per cent to 111 per cent in the early test in which the animals were bleeding freely and the wounds were not being regularly irrigated with frequent wetting of the strips. The value of the ratio for each animal was felt to be correct for such animals. The final values varied from the control sides 1 to 25 per cent and 100 per cent in different rabbits.

of air. Immediately after the animal had expired the skin was stripped from the abdomen. Careful note was made at this time of the presence or absence of any serous blood, or purulent accumulation near or on any of the wounds of the rectus muscles also any gross evidence of stitch infection.

Next the entire abdominal wall was excised and placed on a moist towel to prevent drying. This block of tissue was pinned to a cardboard beneath the towel to prevent the specimen from slipping during the process of sectioning into strips. The tissue was then cut into strips 1 centimeter in width each strip running across the midline through the intact rectus muscle on the opposite side as well. Thus each strip of tissue consisted of a portion of the rectus wound with two silk sutures in place linea alba and the previously undisturbed rectus on the opposite side; the entire transverse piece being 1 centimeter in width and about 4 centimeters long. Using a modified suture testing device (1), the tensile strength of the midline was tested. The mean tensile strength of the sutured portions in each rabbit was divided by the mean value after 15 days of the previously undisturbed side to determine the per cent ten-

WOUND STRENGTH
Per cent of previously undisturbed side

Fig. 2. The tensile strengths of silk-sutured abdominal wound in rabbits at various periods after repair. The smooth curve gives in most instances within 6 times the standard deviation from the mean from the average for each time period, and in all cases within the width of the standard deviation from the mean.

strength of the wound. Usually 10 determinations were made on each side of each rabbit. Between 4 and 18 rabbits were tested for each period's determinations. An average of all percentages was taken for all the rabbits tested at a specified period to plot the curve of wound healing.

Where there was any evidence of gross infection or abnormal appearance of the wound the rabbit was not used in the curve. Microscopic sections of all wounds tested were made and studied. Here too, when there was any evidence of infection or variation from normal wound healing the determinations were not included.

Tensinometer. We were unable to find in the literature a description of a tensiometer adequate for our purposes. One was therefore devised on the basis of the general principle employed for the suture testing apparatus.

previously reported by one of us (1). A stout spring is stretched by tension on the strip of tissue to be tested. The rupture tension is recorded by a free rider which remains at the point of maximum tension after rupture has occurred (Fig 1).

At the conclusion of these experiments a tensiometer of German make was found described in Sandblom's paper (8) on skin healing. It has the added factor of constant rate of increase of tension prior to rupture, and is therefore probably superior to the one we have used.

RESULTS

The first difficulty encountered was wound infection. Routine gross examination of wounds and microscopic examination of one segment of each wound resulted in the discard of 17 animals on this basis and 1 on the basis of hemorrhage into the wound.

It was found possible to construct a smooth curve of strength gain which falls well within the limits of the standard deviations from the mean value for each time period (Fig 2 Table I).

At the completion of closure the wound with sutures present was 41.9 per cent as strong as the previously undisturbed opposite side. This value dropped very slightly during the next 3 days, and then rose sharply approaching 80 per cent at 15 days and rising significantly no more after that point.

Certain variations in these results were found to attend variations in type of suture material including catgut, and manner of placement. These are the subject of further studies by 2 of us (Carleton Nelson and John Fast) and will be reported in later communications.

CONCLUSIONS

1 The strength at varying periods of the healing wound plus the sutures employed is of paramount interest to the surgeon in the light of the present trend toward early ambulation.

2 In rabbits, the strength of the freshly silk-closed abdominal wall wound is about 40 per cent of the undisturbed opposite side and remains at this value 3 days. Thereafter it rises steeply to about 80 per cent at 2 weeks.

3 In the 6 weeks of observation in rabbits, silk-closed wounds never regained full preoperative strength remaining at about 80 per cent of that value.

SINCE the introduction of dry glove technique now almost universally employed by surgeons everywhere the powder used on rubber gloves has been under some degree of suspicion. But since any ill effect it might produce was masked by other more obvious factors such as infection, trauma, or suture material it attracted comparatively little attention. The incrimination of lycopodium powder as the causative agent in many granulomatous lesions and intra-abdominal adhesions is now too well known to require detailed review. The historical aspects of this subject have been ably presented by Seelig Verda, and Kidd (13). The use of lycopodium powder was rapidly abandoned in favor of magnesium silicate or talc. This inorganic material was thought to be physiologically inert in contact with living animal tissue and is now generally employed as a dusting powder for surgeons' gloves. With recognition of silicosis as an industrial disease entity some interest was aroused in the possibility that talcum powder might not be entirely innocuous. In 1933 Antopol reported 2 cases of granuloma due to talc—one in the neck and one in the serosa of the appendix. These 2 cases were mentioned in passing in a report on lycopodium granuloma and the possibility was suggested that unrecognized talc granuloma might be quite common. Feinberg reported 2 cases of talc granuloma in 1937 and for the first time employed polarized light both to demonstrate and to identify the crystals responsible for the lesions. He injected small amounts of talc suspended in saline into three mice and produced granulomas, but no adhesions, and warned against the indiscriminate use of talcum powder in the operating room.

Although scattered confirmatory reports (2, 4, 6, 10, 11) appeared in the literature, little attention was paid to them by clinical surgeons and in 1943 a second and quite comprehensive article by German (7) emphasized the danger of granuloma formation but minimized the tendency to form intestinal adhesions. In 40 of 50 unselected patients who were subjected to a second laparotomy German found intra abdominal granulomas which he proved by means of polarized light to be the result of foreign body reaction to talc. Although there was a close parallel between the number of adhesions present and the number of granulomas the adhesions were attributed entirely to collateral causes. He stated "In the mechanism of the formation of adhesions it is well known that fibrin plays an important part. The inability of silica *per se* to induce an exudation of fibrin would suggest that it is not important in the formation of adhesions. These observations would point to a very efficient mechanism for disposal of talc by the peritoneum."

German based his conclusions on the intra peritoneal injection of a 0.5 per cent saline suspension of talc into mice and on dry powder application in which he used only one test rabbit and one control rabbit, with and without trauma. He produced granulomas, but no adhesions. On this basis he concluded that

Talc *per se* in the abdomen in the absence of injury to the peritoneum is quickly removed from the peritoneal cavity, immobilized and covered with serosal cells, without the formation of an exudate and without adhesions. Adhesions do not develop without some form of traumatization of the peritoneum sufficient to produce exudation of fibrin. Even in the presence of peritoneal trauma and exudation of fibrin the talc plays a secondary rôle, in that it is caught up in the fibrin and is incorporated in the adhesions. Thus the developing granulomas may either add to the bulk and density of the developing adhesions or may

impede the resolution of any adhesions once formed. In this sense it may be said to contribute to the disability produced by adhesions resulting from surgical operations.

It remained for Seelig (12-13) to re-emphasize strongly the danger of talc as an adhesion producing agent. Although mice are notoriously recalcitrant to the production of adhesions he was able to produce generalized adhesions quite uniformly in a large series (104 mice) in which 2 cubic centimeters of a 5 per cent saline suspension of talc was injected intraperitoneally. He tested some 24 different powders and selected potassium bitartrate as a nonreactive substitute. Later he employed a starch powder which was said to withstand autoclaving fairly well. This represents the first reported use of a starch derivative for this purpose and our studies constitute an extension of Seelig's work with certain modifications in methods and materials.

In a comprehensive and detailed study Lichtman, McDonald, Dixon and Mann have shown that talc is not an inert foreign body. They point out that commercial talcum is a mixture of talc, serpentine, dolomite or tremolite. Talc itself is a hydrous magnesium silicate. The material leached out of a talc crystal is not the same as the parent substance. The degree of hydration of this derivative substance determines its toxicity. For ex-

ample a mole of alpha silicic acid may bind as many as 300 moles of water. The size, shape, and cleavage of a talc particle and its surface energy affect its so called solubility. In the body alteration of the pH and the presence of protein in tissue fluids alter the size and characteristics of the dispersed aggregates. By means of the now common use of polarized light they conducted an extensive study of the pathogenesis of talc granulomas and adhesions, resulting from dispersed talc particles 0.5 to 10 microns in size.

The greatest barrier to the abandonment of talcum as a glove dusting powder has been the lack of an acceptable replacement for it. Many powders have been studied and the commonest single defect in those which are physiologically safe has been a tendency to gelatinize or agglutinate in the autoclave, thus defeating the primary purpose of the powder, namely to lubricate gloves and hands.

A further barrier to replacement of talcum powder has been a general failure fully to appreciate its danger. In most hospitals surgeons do not even take the precaution of washing the powder from their gloves before operating.

The purpose of our study was to verify the increasing evidence that talcum powder is a dangerous agent in human surgery and to evaluate certain proposed replacements for it.

EXPERIMENTAL STUDIES

Physical properties. Preliminary selective studies were made on the physical properties of ten powders, with commercial talc as the control.

The powders (Table I) used in this study were made available to us by the Department of Clinical Research, Ethicon Suture Laboratories, Division of Johnson and Johnson, New Brunswick, New Jersey. The first four powders have already been tried out by other investigators (7-11) and were included for comparative purposes. The last four powders, designated 100, 101, 107 and 108 are derived from corn starch which has been treated by physical and chemical means to prevent gelatinization in the autoclave. These four powders differ substantially only in degree of treatment, except that numbers 107 and 108 have

had a special chemical treatment to improve their lubricating value. The identity of the remaining powders in Table I is self-evident.

The fineness and flow and dusting qualities of the raw powders were arbitrarily classified by gross estimation from + to +++++ the latter representing the greatest freedom of flow and ease of distribution in dusting gloves and hands. Samples of each were then autoclaved under 15 pounds of pressure for 15 minutes and retested. The results are shown in Table I.

Examination of these results shows that powders 100 and 101 were about comparable to talc and that powders 107 and 108 and tantalum oxide were superior with respect to physical qualities after autoclaving. No experiments on tissue tolerance were conducted with the group of powders showing inferior physical qualities. Powder 107 was also eliminated because since No 108 was known to represent a further refinement of it detailed study became an unnecessary duplication. Tissue tolerance studies were therefore conducted on powders 100 101 103 A (tantalum oxide) and 108, with talcum (104) as a control.

Method of testing peritoneal reaction. Dogs were selected as the test animals because actual operating room conditions could be closely approximated and because the peritoneal reactions of dogs more nearly approach human reactions than do those of mice, rats, guinea pigs, or rabbits which have been used in studies heretofore reported by others. In a further effort to duplicate operating room conditions, dry powder was used in open operation rather than by injection in a saline suspension.

In every operation the abdomen was opened through a standard rectus incision. Rigid aseptic technique was employed throughout, except that before beginning the operation both operator and assistant washed their gloves thoroughly under running tap water. In every operation the small bowel was run from Treitz's ligament to the ileocecal valve. When a powder was being tested it was dusted as evenly as possible over the bowel and both mesenteric surfaces as the bowel was run. When the last loop had been handled or treated the abdominal wound was closed in layers with silk.

TABLE II.

Equivalent washings from operating room gloves	Weight in grams	Volume in teaspoon measures
2 pairs	0.26	1/4
4 pairs	53	1/2
8 pairs	1.024	1
6 pairs	2.01	1

After an interval of 3 weeks each dog was reopened the same technique being used and explored for adhesions. When few adhesions were found a careful count of them was made after the method of Lehman and Boys (13). When adhesions were too numerous to count they were designated +++ or +++++ denoting generalized massive adhesions.

Quantity of test powder. In order to arrive at a suitable quantity of powder for test purposes 4 pairs of gloves were drawn from the ready supply in the operating rooms of the University of Virginia Hospital. The outer surfaces of these gloves were washed as thoroughly as possible under a single washing with a fixed quantity of water.¹ The water was then evaporated and the residual powder was found to weigh 0.5262 gram. This was taken as the maximum amount of powder with which the peritoneal cavity might be contaminated by an operating team of four persons, if only one pair of gloves were worn by each and if none of the gloves was punctured.

Since the powders to be studied were of different specific gravities a volumetric measure was considered better for comparative purposes. A set of kitchen teaspoon measures was employed and approximate values were obtained for talc (Table II).

One-half teaspoonful represents the amount of talc from 8 pairs of gloves. On this basis in order to make the tests sufficiently rigorous this amount was selected as the dose to be dusted over the peritoneum of dogs. Certain exceptions to this dosage will be noted under results.

Bacterial studies. Although it had already been shown that the physical properties of powder 108 were not impaired by autoclaving it seemed desirable to establish that this

¹It is of interest that when these washed gloves were air-dried they were still abundantly covered with a fine coating of powder.

Fig. 1. Small bowel of dog treated with talcum powder. The bowel and mesentery has been removed and laid over the end of bucket. Adhesions are so numerous and dense that the coherent mass hangs together like a cap.

powder (which will be shown to have a high order of tissue tolerance) could in fact be effectively sterilized.

Through the courtesy of Dr Frank Meleney a laboratory at Presbyterian Hospital New York some spore threads were obtained of a highly heat resistant strain of *Bacillus subtilis*. This strain when the test tube is completely surrounded by the water will withstand boiling for 20 minutes.

A sample of powder 108 as received was autoclaved for 15 minutes at 15 pounds pressure. Culture from this sample was sterile.

A second sample was contaminated with heat resistant *Bacillus subtilis* spores and then cultured without autoclaving. *Bacillus subtilis* was readily cultured from the sample.

Fig. 3. Section under low power through an adhesion between two loops of bowel.

A third sample was similarly contaminated and then cultured after autoclaving. Culture from this sample was sterile.

RESULTS

Controls (Table III) No adhesions resulted when no powder was used. When talcum was used dense generalized adhesions were formed. Even when the dose of test powder was reduced to $\frac{1}{8}$ teaspoonful or roughly the washings from one pair of gloves the result was the same.

These dogs were sacrificed and at autopsy the small bowel was removed *en bloc* and formed one cohesive conglutinate mass which, when draped over the end of a bucket, sat on it like a cap (Fig. 1). The small spots of agglutinated talc were readily visible in gross under the adhesions (Fig. 2 (frontispiece)). Microscopic sections taken through sample adhesions showed the talc embedded under the adhesions against the serosa (Figs. 3 and 4). Under polarized light the identity of this material was evident (Figs. 5 and 6). The celiac and superior mesenteric nodes were greatly enlarged. Sections of these were taken to de-

ficiently so to suggest testing the effect of an increased dosage. Two dogs were treated with a full teaspoonful of powder 101 equivalent to washings from 16 pairs of gloves. It is of interest that each of these dogs had been used in a previous series and the increased dose had been put in when they showed no adhesions after the first test. One dog showed no

*One dog had an infected laparotomy wound and showed +++ adhesions. Because of this extraneous factor the average and greatest number of adhesions is taken from the remaining four dogs.

Fig. 6. The same area as in Figures 4 and 5. Here the prisms have been completely rotated blotting out all but the doubly refractile talc particles.

adhesions at his third laparotomy and the others showed only five. Since powder 108 was known to represent a further refinement in processing and since its physical properties were superior the next major series was conducted with this powder. In every case when the dog was opened after 3 weeks not a trace of powder was to be found nor was there a single adhesion present. The bowel when removed *en bloc* was as clean and healthy as if it had never been touched (Fig 5). These striking results indicate the superiority of powder 108 over every other powder tested and are as good as the controls without powder.

CLINICAL EVALUATION

By arrangement with the superintendent of a private hospital in this city powder 108 was installed in the operating room in place of talcum without the prior knowledge of the surgeons working there. The operating room supervisor was asked to take note of any comment they might spontaneously make.

With only one exception every surgeon commented favorably having noticed the improvement in physical quality over the powder previously in use and asked what the new powder was. The single exception made no comment at all favorable or unfavorable and apparently did not notice the change.

In the course of this trial use only one unfavorable feature was observed. It happens that in this particular hospital glove powder is put up in aluminum salt shakers and used throughout the course of a day's operating schedule. Frequently these shakers are not emptied in one day and are reautoclaved and used again the next day. It was noted that while the physical properties of the powder remained unimpaired through one or at most two autoclavings there was some tendency to clump after the third such sterilization. After the fourth or fifth although the clumps were readily shaken out and fine dusting powder could be obtained from the can many residual lumps were left.

This single disadvantage seems trivial in comparison with the many advantages derived from the use of this powder and is easily obviated either by using smaller shakers or by employing the widely used technique of put-

ting up the dusting powder in individual packages with each pair of gloves.

DISCUSSION

It has been shown in our control studies that the atraumatic, aseptic manipulation and handling of the small bowel does not produce adhesions in healthy dogs.

When dry talcum powder is dusted over the serosal surfaces massive dense and uncountable adhesions were produced wherever the talc came in contact with the tissues. This indicates that neither trauma nor infection are required in the presence of talc to produce adhesions and the powder alone must here be held responsible. This is in direct contrast to the observations reported by German.

Furthermore our study of the regional lymph nodes indicates that at least after 3 weeks any effort on the part of the body to remove the powder via the lymphatics has been unsuccessful.

Our observations on the test powders indicate that powder 108 is completely absorbed from the peritoneum without any demonstrated inflammatory reaction and that it produces no adhesions whatever.

The fate of this powder does not offer any great pharmacological problems (3). Since it is a corn starch powder it is simply taken up by the peritoneum and metabolized like any ingested starch. Its advantage over raw starch and other treated starches is that its dusting, lubricating and flow qualities are not adversely affected by autoclaving. Its superiority over talcum powder, tantalum oxide or any other mineral, metallic or nonmetabolized powder is obvious.

MacQuiddy who has investigated the sensitizing properties of this substance both in human patients and in animals, has failed to demonstrate under experimental conditions any sensitizing or anaphylactogenic properties. However subcutaneous tissue sections obtained by MacQuiddy indicated that in some instances at least complete absorption of the powder had not occurred at the end of 36 days. In such cases, relatively large compact masses (up to 200 mgm) had been embedded and under such circumstances absorption might be expected to be slow and

difficult. MacQuiddy's studies are being continued and will be reported in detail at a later date

CONCLUSIONS

1 Further evidence is presented that talc is a deleterious substance in living tissue, that it produces a violent peritoneal reaction and dense adhesions and that its use as glove dusting powder is dangerous.

2 A commercially prepared dusting powder is shown experimentally to have

a. Excellent physical qualities of flow and fineness, unaffected by autoclaving

b. Complete absorption by the peritoneum without inflammatory reaction and without the formation of adhesions

c. Complete sterility under standard autoclaving procedure after known contamination with spores of a heat resistant organism.

3 A brief clinical trial of this powder has been entirely satisfactory

EXPERIMENTAL IMPLANTATION OF THE COMMON BILE DUCT INTO THE INTESTINE

FREDERICK M BINKLEY M.D., ROBERT PALMER, M.D., and
H J McCORKLE, M.D., F.A.C.S. San Francisco, California

CLINICAL and experimental surgical procedures in which the bile duct is implanted into the intestinal tract have been employed with increasing frequency in recent years. It is desirable that biliary intestinal anastomosis be done in such a manner as to prevent leakage of bile into the peritoneal cavity in the early postoperative period and to avert the later postoperative complication of cholangitis which often is associated with stricture at the site of anastomosis, stasis and infection of bile, and probably with reflux of intestinal contents into the biliary duct system.

In consideration of these points several types of experimental implantation of the common bile duct into the intestine of dogs were performed in an attempt to develop an efficient, simple procedure.

The experiments were divided into four main groups

1 *Simple implantation* Choledochoduodenostomy was done in 13 dogs, 8 of which had a normal common bile duct. In the remaining 5 animals the common bile ducts were ligated at a preliminary operation. Two or 3 weeks later these animals were reoperated upon and the dilated common bile ducts were implanted into the duodenum.

The technique of implantation of the bile duct into the duodenum is illustrated in Figure 1. After the bile duct is ligated and dissected free a single row of interrupted cotton sutures is placed posteriorly approximating the duodenum and the posterior wall of the common duct at a distance of 3 to 5 millimeters from the free end of the duct. The posterior row is tied under direct vision, in

order to insure accurate serosa to-serosa approximation. Two incisions are then made in the duodenum one just anterior to the suture line and with a curved hemostat which is passed through the two incisions, the common duct is drawn into the lumen of the duodenum. An anterior row of interrupted fine cotton sutures is placed completing the serosa to-serosa anastomosis. The ligature is cut from the distal end of the duct, leaving a free end from 2 to 4 millimeters in length extending into the lumen of the duodenum. The second incision is closed with 1 or 2 interrupted cotton sutures.

In none of these animals was there evidence of leakage of bile from the anastomosis in the early postoperative period. The postoperative course was not remarkable except for the urinary findings. In most animals daily urinalysis revealed the presence of bile during the early postoperative period but the urine invariably was free of bile by the 10th postoperative day. In order to determine the cause of the transient jaundice 3 animals were sacrificed on the 5th postoperative day. In these animals the common bile ducts were found to be somewhat dilated. There was considerable edema at the site of anastomosis and in the surrounding duodenum. In all cases bile flowed spontaneously into the duodenum.

The remaining 10 animals were sacrificed from 34 to 338 days after the choledochoduodenal anastomosis (Table I). In these animals the anastomosis was found to be well

Fig. 2 Photomicrograph of anastomosis demonstrating mucosal junction of common duct and duodenum.

healed and appeared to be functioning satisfactorily. There was no evidence of stenosis. The mucosa of the common duct appeared to be continuous with the duodenal mucosa and the orifice usually lay between mucosal folds. Histological sections showed the ductal and duodenal mucosa to be directly continuous, and several histological sections revealed elevation of the duodenal mucosa about the stoma, forming a papilla like structure. There was a minimal fibroblastic response and no evidence of chronic inflammation (Fig. 2). X ray studies failed to demonstrate regurgitation of barium or free air into the extra hepatic biliary passages (Fig. 3).

¹Causes of death, peritonitis, 1; cholangitis.

Fig. 3 Roentgenogram following simple hepaticoduodenostomy. Gastrointestinal series consistently failed to demonstrate regurgitation of barium or free air into biliary passages.

There were 3 deaths in this group. Two were caused by an overdose of sodium pentobarbital used for anesthesia. One animal died with peritonitis on the 15th postoperative day but there was no apparent leakage of bile from the anastomosis. The origin of peritonitis in this animal probably was contamination with intestinal flora at the time of operation.

3. *Simple implantation into blind limb of jejunum.* In the second group of 5 animals the common duct was implanted into a blind limb of jejunum (the Roux arm principle being utilized) the same method being used as described for the first group of animals (Fig. 4). In dogs satisfactory fixation of the blind jejunal limb was difficult to obtain and the anastomoses were unavoidably under considerable tension. In 3 of the 5 animals results were satisfactory and the findings were similar to those described in the first group (Table II). There were 2 deaths. One animal died on the 3rd postoperative day with diffuse peritonitis;

Fig 4. Simple Implantation into blind limb of Jejunum. A, Simple implantation of duct. B Completed procedure showing implantation into blind limb and end-to-side jejunal anastomosis.

the anastomosis was not healed and there probably was leakage of bile into the peritoneal cavity. The other animal died with acute cholangitis on the 5th postoperative day. The anastomosis was found to be healing satisfactorily with no leakage of bile. The bile ducts were filled with thick, mucopurulent exudate.

3. Anastomosis using mechanical support
In a group of 5 animals a dilated (previously ligated) common bile duct was anastomosed to the duodenum over a mechanical support (Fig 5).

In 2 animals the anastomosis was done over a rubber catheter and in 3 a flanged tantalum

metal tube was used. In the cases in which a rubber catheter was used, one dog was sacrificed on the 10th, and one on the 44th postoperative day (Table III). The anastomoses were well healed and appeared to be function

ing satisfactorily. In one animal the duct wall was thickened and there were numerous adhesions and an increased amount of scarring about the anastomosis. Histological examination revealed a marked increase in connective tissue reaction and inflammatory response when compared with similar sections from implantations in groups I and II (Fig. 6). Two of the 3 animals in which a tantalum tube was used died, one on the 12th and one on the 30th postoperative day. The former was found to have peritonitis resulting from a perforation of one of numerous liver abscesses, and the latter died with pneumonia. In both animals the anastomoses were well healed and appeared to be functioning satisfactorily and the tantalum

tubes had remained in their original position. The third animal was sacrificed on the 12th postoperative day at which time the tube was found to have passed from the site of anastomosis through the intestinal tract. The anastomosis was functioning satisfactorily. However the duct wall was thickened, and histological sections demonstrated an increased amount of connective tissue about the anastomosis with a moderate inflammatory reaction.

4. *Anastomosis using reinforced fascial tube.* In 3 animals the common bile duct was divided at its junction with the duodenum and the defect was replaced by a tube of cat intestine reinforced with a fine tantalum mesh. At a preliminary operation a rectum

Fig 6 Photomicrograph of area adjacent to anastomosis performed over rubber catheter demonstrating surrounding connective tissue reaction.

Fig 7 Construction of fascial flap reinforced with tantalum mesh. Flap of rectus abdominis sheath turned back over square of tantalum mesh and sutured into position

lar flap of rectus sheath was dissected free and folded back over a square of tantalum mesh placed upon the anterior surface of the rectus abdominis sheath and sutured into position (Fig 7). In this manner the sheet of tantalum mesh was covered on its anterior surface by the flap of fascia and on its posterior surface by the anterior wall of the rectus sheath. Two to 3 weeks later this double thickness of fascia, reinforced with tantalum mesh was excised and fashioned into a tube, which was then anastomosed at one end to a dilated common duct, and at the other end to the duodenum. The anastomosis was performed about a rubber catheter which was left extending into the duodenum and portions of omentum were brought about the anastomosis (Fig 8).

These 3 animals were sacrificed at intervals varying from 119 to 251 days postoperatively (Table IV). At necropsy the anastomoses were found to be surrounded by abundant

vascular adhesions. In all 3 animals the anastomoses were patent and appeared to be functioning however the extrahepatic biliary system was distinctly dilated. The rubber catheters were noted to have passed into the gastrointestinal tract. The tantalum mesh tube protruded into the lumen of the intestine for a distance of 2 to 3 millimeters and was almost entirely covered with duodenal mucosa. The tubes on being opened were found to be almost completely lined with mucosa, however, there were spotty areas through which the tantalum mesh was visible. A relatively thick fibrous wall surrounded the tube which

apparently was not constricted due to the presence of the tantalum mesh.

SUMMARY

1. A simple type of biliary intestinal anastomosis has been done in 18 experimental animals. It may be done rapidly and has given good functional results with minimum inflammatory reaction at the site of anastomosis.
2. Anastomoses employing a rubber or metal tube have been done in 5 experimental animals and these anastomoses invariably have exhibited evidence of considerable inflammatory reaction, scarring and stenosis.
3. An experimental method for the replacement of a defect in the common duct of

animals by a graft of fascia reinforced by tantalum wire mesh is described.

4. It appears desirable to use the simplest possible type of anastomosis (as described in group 1) in situations where a sufficient length of the common duct remains to permit direct implantation of it into the duodenum. Use of the Roux arm principle may not be required in all instances, and might be limited to situations in which the presence or possibility of cholangitis is a factor.

5. The use of metal or rubber tubes for mechanical support in choledochointestinal anastomosis should be avoided if possible because of their tendency to produce marked scar tissue reaction with stenosis. However it

is acknowledged that there are many situations where such support is essential. In such instances temporary support with a very soft rubber tube appears preferable to more permanent support with rigid metal tubes

PRINCIPLES INVOLVED IN SURGICAL THERAPY OF 'ENCAPSULATED' FIBROSARCOMA OF SOFT TISSUES

WALTER W. CARROLL, M.D., Chicago, Illinois

IT is an established fact that success in the treatment of any malignant disease depends to a great extent upon a knowledge of its origin and course. This means that the institution of adequate surgical measures based on this knowledge is just as important as the early recognition of the presence of the malignancy. Even though it is the pathologist's responsibility in the average instance to make the actual diagnosis of malignancy when the surgeon is in doubt, it is the surgeon who has undertaken the responsibility to effect a cure. Having undertaken this responsibility it seems logical that he should be expected to possess as complete a knowledge as is practical concerning the pathological entity at hand. When this pathological entity happens to be a sharply delimited tumor found arising from the soft tissues of the body—that is, from the subcutaneous tissue, muscle or intermuscular fascial planes, the gross appearance of this tumor may lead to the impression of a relatively benign process before the pathologist has had an opportunity to declare himself. It is not too unusual that the same impression may be common to both individuals even after using the time saving device of frozen section tech-

nique for histological study with the result that both are temporarily lulled into a false sense of security. Under such circumstances the definitive surgical extirpation results in a simple enucleation of an apparently encapsulated tumor from its bed of areolar tissue. The postoperative clinical impression in such instances agrees with the preoperative diagnosis of perhaps a fibroma until the permanent sections are examined by the pathologist. If the final diagnosis happens to be 'fibrosarcoma of low grade malignancy', the surgeon is faced with the problem of considering the original surgery as being adequate or of choosing a waiting game. Since tumors spread in the human body only by actual dissemination of viable cells or are manifest in more than one part of an area through a multicentric origin, the correct decision in this instance will be dependent upon an accurate and full knowledge of the disease process.

PATHOLOGY

The histological studies of the last few decades have made considerable progress in distinguishing among the various tumors once collectively known as fibrosarcoma. In the course of this differentiation an expected amount of controversy has taken place among pathologists, out of which has arisen a fuller knowledge of the growth characteristics of

Fig. 1. Three examples of fibrosarcoma each of which presents a well defined fibrous capsule despite the variation

in cellular structure of tumor a, highly cellular type; b, fibrous type; c, fibromyxomatous type.

these neoplasms. Many forms of spindle-cell sarcoma now prove on closer investigation to belong to groups of tumors arising from nerve structures, muscle fat or synovial tissue. In other words, it now appears that practically all of the sarcomas of the soft parts are derived from specialized tissue cells and not from the supporting fibroblasts. The fascial sarcomas of Virchow⁷ thus remain as one of the few pure forms of fibroblastic sarcoma even though modified by lipomatous or myxomatous degeneration whereas an excellent example of this recent clarification is represented by the synovial sarcoma group. The synovial tissues are generally agreed to have arisen from mesodermal tissue but they normally are composed of an endothelial layer and an outer fibrous layer. The tumors arising from this tissue thus fall into two microscopic types. The first are those arising from the inner layer and are more epitheloid in character while the second are those arising from the outer layer and are usually indistinguishable from the common fibrosarcoma. On the other hand, all gradations of specialized fibroblastic tumor formation now considered as of neural origin may be obtained by a complete study of the pathological possibilities found in von Reck-

linghausen's disease with its significant incidence of malignant degeneration. Such a study reveals that the solitary neurofibroma, the neurinoma and the neurogenic sarcoma all arise from the cells of the sheath of Schwann, that is, from the connective tissue coverings of peripheral and central nerves.

Despite this microscopic differentiation all of the malignant tumors here mentioned manifest sufficiently similar gross characteristics to warrant saying that with few exceptions they present the same common problem to the surgeon. Since they present this common problem we feel justified in discussing them under the common heading of encapsulated fibrosarcoma of the soft tissues.

Most fibrosarcomas arising from soft tissues (except those of retroperitoneal and intraperitoneal origin) usually stem from subcutaneous or intermuscular fascial tissues and even though somewhat low in general incidence their gross appearance of apparent encapsulation is known to surgeons (Fig. 1). It is not uncommon to find them densely adherent to tendinous aponeuroses, this frequently seeming to be the apparent point of origin. We have noticed that these tumors frequently encompass an occasional nerve trunk of moder-

ate size along with the accompanying blood vessel, but whether this could be considered as a demonstration of nerve origin is difficult to state without histological study. The fibrosarcoma and the synovioma have in our experience been single tumors sharply outlined from the surrounding tissues, growing expansively and conforming in outline to the area in which they lie. The neurosarcoma on the other hand may be of unicentric or multicentric origin presenting the same encapsulated or circumscribed appearance. When multiple the localized nodules arising from different parts of the same nerve may fuse with one another so that adjacent nerves running in fascia or muscle may become incorporated in the tumor process in such a manner as to give rise to a false impression of infiltration. When nerves are involved primarily or secondarily there is remarkable preservation of function.

There is no one characteristic gross appearance of these tumors as regards color consistency or size since these qualities depend entirely on the relative cellular or fibrous content as well as on the presence of internal hemorrhage, necrosis or myxomatous change which in turn may be dependent upon the primary rate of growth of the tumor. Ulceration is usually a very late finding unless the tumor growth is of such unusual rapidity that it outstrips its own blood supply.

RECURRENCES

It has often been stated by way of definition that fibrosarcoma is a tumor arising from connective tissue characterized by a tendency to recur after excision. Taylor and Nathanson recently reviewed 246 cases covering a period of 25 years. Of this group 62 per cent represented recurrences when first requesting their treatment and of the remaining 97 primary cases local control of the disease was effected in only half the patients. One feels that recurrence or persistence of the disease has become an accepted fact when discussing this type of tumor. It is this tendency toward local recurrences that has limited surgical effectiveness in the therapy of the disease. Were this controlled then an increasing number of patients would be salvaged before the well known blood borne fatal metastasis takes place.

Fig. 2. Fibromyxosarcoma presenting a well defined capsule with attachment to nearby muscle due to tumor cell permeation resulting in partial destruction of the capsule.

Study has shown that in general there are four different microscopic mechanisms, any one two three or four of which may be instrumental in the production of the recurrence. The first and probably most common, mechanism is that of extension of the tumor through its capsule with quite minor involvement of a nearby structure. This is far more obvious to the microscopist than to the surgeon. Although this may be overlooked in the gross specimen it may be noted on careful examination as a point of minor adherence to nearby muscle or it may occur at the apparent point of tumor origin (Fig. 2). In general these tumors grow in the direction of least pressure but despite this advantage to the host, the point of origin or any other point of attachment may present areas in which the tumor has penetrated the capsule, even dissolving it at times to invade the surrounding tissue with the capsule appearing grossly intact (Fig. 3). A pseudocapsule may even form to confuse the gross picture there being a layer of fibrous tissue thrown up in front of the advancing tumor. Such permeation of tumor cells produces a focus which if left *in situ* will be a nidus for local recurrence.

The second mechanism pertains to the factor of lymphatic spread. This is a neglected subject because lymph node involvement typically occurs late in the course of the disease, although in 1926 Hertzler reported a patient with early involvement. It has been noted as high as 8 per cent in a series of 256 cases.

Fig. 3. a, left, Penetration of fibrosarcoma through its own capsule. b, The spread of cells at the apparent

point where the tumor had its origin from the fibrous perineurium.

Long duration large size of the primary tumor local recurrence after excision and ulceration are prominent findings in proven instances of lymphatic metastasis. There is no doubt but that the tumor is slow to reach the larger lymphatic regional collecting depots, but the fact that such does occur must make one realize that involvement of lymphatic channels in the areolar tissue about the tumor at the time of excision is a potential hazard for recurrence. Under such circumstances local as well as distant spread of the tumor becomes more likely during the surgical procedure since many new tissue spaces are laid open to the tumor cells.

The third mechanism concerns the concept of multicentric origin of some of the tumors. This follows from the original observations made by Geschickter (3, 4) and by Stewart and Copeland. Working with neurogenic sarcoma they have noted the frequent development of a tumor after surgery higher up in the nerve trunk. Geschickter concluded that this represented an extension from the original tumor along the perineural lymphatic spaces. In the same manner he implicated the perivascular lymphatics of large vessels which were connected with the main tumor mass. On

the other hand Stewart and Copeland have considered such a neoplasm to be an independent new growth arising in the condensed segment of the same nerve, thus attributing a certain tendency toward malignant degeneration to the nerve structures. In studying the malignant changes in 466 patients with von Recklinghausen's disease, Hosoi has shed light on the problem by stating:

In résumé malignant transformation takes place in about 13 per cent of all cases of von Recklinghausen's disease. When this happens, the tumor grows rapidly and tends to recur locally even after repeated operative measures. In some cases the more extirpation of a malignant tumor or even a benign one appears to stimulate another neurofibroma distantly located to undergo sarcomatous transformation."

The accompanying photomicrographs present an excellent example of multicentric origin of malignant neurinoma arising within the intermuscular fascial planes of the erector spinae muscle group (Fig. 4). The differential identification here lies between a lymphatic metastatic nodule lying in the soft areolar tissue surrounding the primary encapsulated tumor and a second primary neoplasm arising in a nearby branch of the same nerve from which arose the original neurinoma. Close micro-

Fig. 4-a, left, Second primary malignant neurofibroma found in arcolar tissue surrounding an encapsulated neurofibroma of the back b Higher magnification shows the

mimicry of structure including the slight fibrous capsule. The tumor apparently did not reach within a lymphatic channel.

scopic study makes the latter opinion the more tenable.

The fourth mechanism concerns the now well substantiated phenomenon of autotransplantation or implantation at the time of surgery due to spillage of tumor cells into the wound. The experience of Harrell and Volk is cited in this regard. These men reported an accidental autogenous transplantation of an ulcerated fibrosarcoma of the heel to the left thigh during the application of a pedicle skin graft. This was explained as due either to direct extension of the tumor through the graft or by accidental contamination of the incision at the donor site with tumor cells. The experience of Greene in successfully transplanting human fibrosarcoma to the anterior chamber of the eyes of guinea pigs and carrying it by serial transfer through 14 generations adds further weight to this concept.

TREATMENT

Before considering the application of these observations as they might be related to therapy it is of interest first to note the report of Meyerding, Broders and Hargrave covering a 20 year span in which they recorded a 3 year survival rate of 21 per cent in 132 patients afflicted with fibrosarcoma. Since it is now generally agreed that radiation therapy is of little value (1, 12) the obvious conclusion to be drawn from such a pessimistic report as well as our own experience is that the primary surgical attack on these tumors appears to be

inadequate in many instances. For these tumors located in the extremities one might easily conclude that the percentage of cures could be increased by routine amputation but closer examination of a large series of cases reveals that this would result in an unnecessarily large number of amputees without materially lowering the death rate. Thus Meyerding and his co-workers reported that of 28 cured patients in their series only 6 had amputations performed. There is no doubt but that amputation is absolutely mandatory when complete excision is impossible, when deep nerves or vascular trunks appear to be involved or when recurrence has taken place for the first or second time. Even in this last mentioned group where recurrence has taken place, Meyerding reports but five cures in 34 instances where amputation was performed in the absence of demonstrable metastases. We realize that proper evaluation of available statistics on amputation for these tumors is difficult because of the previous inaccurate histological differentiation and also since this maneuver usually has been reserved for the advanced cases, but nevertheless the procedure does not seem to fit all the requirements for the patient requesting primary care.

The answer to this low rate of cure seems to lie in the performance of a more complete local excision at the time of the first surgery. In a negative way this means that the tumor should not merely be shelled out of its connective tissue bed. In a positive way this

means that the tumor and its areolar tissue bed plus any attached muscle, nerve, or blood vessel should be excised *en masse*. Blunt dissection here is not the answer. In reviewing the operative reports concerning the removal of some of these tumors, we have noted that the tumor frequently was shelled from its bed down to an apparent point of origin or at least to a point of attachment from which it was cut free with a scalpel. Because of the lymph drainage within a muscle, it is felt that partial excision of muscle may be inadequate when a muscle belly appears to be invaded. In such instances our experience would lead us to suggest that complete extirpation of the muscle or group of muscles is far superior to a recurrence. Section of nerve trunks and ligation of vascular highways should best be performed as far as possible from the tumor. If involvement of these structures presents insufficient indication for amputation then the least we can advise is wide excision and restoration of nerve continuity with fresh autogenous or homogenous grafts. The logic of such a procedure has been clearly demonstrated (2). With the more prevalent ability in skin grafting there seems to be no excuse for allowing any possibility of recurrence by cutting too close to the tumor when excising overlying skin.

APPLICATION OF SURGICAL EXCISION

From the practical standpoint these generalities, if accepted, must be reduced to terms of procedure for the individual patient. In other words some consideration must be made concerning the incision to be used as well as the part to be played by the pathologist if needed in establishing the diagnosis. These steps must be carried out with sufficient ease and safety to allow for the most efficient surgical extirpation possible. Our feeling at this time is that most tumors found in the areas mentioned eventually are proved to be malignant following microscopic study. Very few instances of purely benign tumors can be found among such a group except for the fibromas with their characteristically long history and small size and the lipoma which is quite easily identified. Willson found that 90 per cent of 111 specimens of fibrosarcoma measured over 5 centimeters in greatest diam-

eter while the same percentage of fibromas measured under 3 centimeters. Such information may be helpful but not unless correlated with duration and rate of growth. Certainly any small subcutaneous nodule which has persisted for years and which suddenly begins to grow rather rapidly will be suspected of malignant change before it reaches the critical size of 5 centimeters.

If the diagnosis is obvious a more vigorous attack can be planned at the earliest phase of the surgical intervention. There is no doubt but that the element of surgical judgment is prominent in such a matter and for the sake of clarity it is logical to liken this problem to that of breast carcinoma. In many instances the experienced surgeon can with the fullest justification proceed with his radical mastectomy without the aid of a frozen section because to him the pathological diagnosis is quite evident while in other instances he will rely upon the microscope following a local excision before going on with the more radical procedure. Unfortunately the pathologist finds himself at a disadvantage with the frozen section technique when attempting to diagnose some of these tumors without the use of special stains. Theoretically this very practical procedure loses some of its utility but this does not mean that it should be omitted from our armamentarium when we are in doubt, for it can establish in a general way the degree of malignancy that an individual tumor may possess. By this we mean that a "mad dog" type of tumor can be differentiated from a "sleeping dog" type irrespective of the cellular origin. The relative proportion of cells to fibrillar intercellular substance is probably the best single criterion for estimating the degree of malignancy in these tumors.

SUMMARY

The high mortality rate in patients afflicted with fibrosarcoma presents a severe challenge to the surgeon. Some of these patients probably never will be cured but many can be salvaged by preventing fatal blood-borne metastasis. This form of metastasis appears to be related to the incidence of local recurrence more than to the incidence of the disease. The local extirpation of the disease thus becomes

of paramount importance. Since the tumor frequently occurs in the extremities the question of amputation also must be considered among the methods of obtaining local control of the disease. At the present time we feel reluctant to advise amputation when a satisfactory local excision can be first achieved but on the other hand if a careful evaluation of the speed of growth the size location and histological nature of the tumor would warrant it amputation should be carried out as the procedure of choice. If the tumor presents as a recurrence, it is highly likely that a high amputation should immediately be advised unless a more adequately wide excision could still be performed. In such instances, the size of the resulting defect should not be a barrier for adequate excision as long as proper skin replacement can be achieved. It is not possible to outline typical procedures to be followed for each instance but we are impressed with the

fact that the successful outcome in most instances will be determined by the procedure used at the time of the first surgical intervention

PANCREATIC REFLUX DELIBERATELY PRODUCED

HENRY DOUBILET M.D., F.A.C.S. New York, New York

THE importance of biliary-pancreatic reflux as an etiological factor in the production of acute pancreatitis or acute cholecystitis has been amply demonstrated in recent years (1 3 5 7 8 9)

In the past, pancreatic reflux was demonstrated in about 25 per cent of patients in whom a tube was placed in the biliary tract at operation (2 6) The diagnosis was based on two methods (1) the finding of pancreatic enzymes (notably amylase) in high concentration in the bile recovered from the tube drainage and (2) the visualization of the pancreatic duct when iodized oil was injected into the tube draining the biliary tract

These observations frequently depended on a fortuitous conjunction of events. As a rule pancreatic enzymes could be found in the bili-

ary drainage only occasionally usually after meals (2) but sometimes only in samples obtained late at night (Table I). Similarly the pancreatic duct could be visualized during the performance of a cholangiogram only during such accidental periods when the pancreas was not secreting and when in addition the sphincter

Figs. 1 and 2. Before the administration of morphine (Fig. 1) the injection of iodized oil fills out the common duct, then runs into the duodenum. Only the terminal parts of the hepatic duct are outlined. Two minutes after subcutaneous administration of morphine, the continued injection of iodized oil results in the visualization of the whole biliary tract. This is due to the increased resistance of the sphincter of Oddi.

Fig. 3 Kymographic tracing of the resistance of the human sphincter of Oddi. Following the administration of morphine, $\frac{1}{6}$ grain, the normal resistance of the sphincter (150 mm. of water) rises to 300 millimeters and gradually subsides to 200 millimeters in one hour.

ter of Oddi was sufficiently spastic to permit the reflux of iodized oil.

An effort, therefore, was made to determine the optimum conditions under which reflux of pancreatic juice could be routinely obtained and the pancreatic duct could be visualized most frequently during cholangiographic studies.

When the resistance of the sphincter of Oddi is normal (about 150 mm. of water) iodized oil passes through the common bile duct into the duodenum without filling the fine bile ducts (Fig. 1). Two minutes after the subcutaneous injection of $\frac{1}{6}$ grain of morphine (Fig. 2), the whole biliary tract can be visualized. Kymographic tracings (Fig. 3) reveal these pressure changes clearly (4). One can note, however, that the resistance of the sphincter which rises

to 300 mm. of water comes down to 200 mm. at the end of an hour. The intraduodenal injection of hydrochloric acid causes a temporary spasm of the sphincter lasting 10 minutes (Fig. 4). When the sphincter is moderately spastic (Fig. 5) in cases in which the bile and pancreatic ducts join above the sphincter, the iodized oil runs up the main pancreatic duct and out through the accessory pancreatic duct (Santorini) when this duct is present. In the

Fig. 4. The intraduodenal installation of tenth normal hydrochloric acid causes immediate spasm of the sphincter of Oddi. The resistance rises from about 150 to 250 millimeters of water and the effect wears off in about 10 minutes.

Fig. 5. Visualization of the main (Wirsung) and accessory (Santorini) pancreatic ducts. The iodized oil passes down the common bile duct, meets with resistance from the sphincter of Oddi, and passes up the main pancreatic duct of Wirsung and then through the accessory duct of Santorini into the duodenum.

Figs. 6 and 7. Injection of iodized oil shows considerable spasm of the sphincter of Oddi (Fig. 6, left) since the hepatic ducts are outlined to a considerable extent before the oil passes into the duodenum. At the same time, a portion of the pancreatic duct (arrow) is filled. The junction of the common and pancreatic ducts at the ampulla of Vater is clearly visualized. Following the administration of morphine (Fig. 7) the whole biliary tract is outlined. The increased turgidity of the duodenal wall as a result of morphine action causes compression of the intramural portion of both the common and pancreatic ducts. The ampullary junction of these ducts are, however, still clearly outlined (arrow).

following case (Fig. 6) one can clearly see the submucosal junction of the two ducts. Two minutes after the injection of morphine (Fig. 7) the whole biliary tract is outlined due to spasm not only of the sphincter but of the duodenal wall through which both ducts pass.

When the bile and pancreatic ducts are connected by a fully unobstructed passageway as in the following unusual case (Figs. 8 and 9) which Dr. Ralph Colp of The Mt. Sinai Hospital kindly allowed me to study, passage of pancreatic juice into the biliary drainage was

Figs. 8 and 9. Injection of iodized oil reveals a hugely dilated choledochus and markedly dilated tortuous pancreatic duct (Fig. 8). The narrow submucosal junction of the two ducts is clearly seen (arrow). Another view (Fig. 9) outlines the whole dilated pancreatic duct as far as the tail.

Fig. 10. Simultaneous collection of T tube bile drainage (5 tubes on left) and duodenal drainage (5 tubes on right) following the injection of secretin in the case illustrated in Figures 8 and 9. The first tube contains drainage of the 10 minute control period, and the following consecutive tubes drainage of 20, 30, 40, and 60 minutes after secretin stimulation. Note the variations in the density especially of the T tube drainage, due to spurts of almost water clear pancreatic juice mixing with the bile.

of quite frequent occurrence. When secretin was administered intravenously to produce pancreatic reflux under controlled basal conditions, it was found (Fig. 10) that about half the pancreatic juice passed into the duodenum while the other half passed up the common bile duct. Gushes of almost water clear bile (containing pancreatic juice) would

Fig. 11. Concentration of amylase in T tube and duodenal drainage following the intravenous injection of secretin in the case illustrated in Figures 8, 9, and 10. The variations in the amylase content of the two drainage fluids appear to be related to the changes in the volume of secretion.

alternate with darker bile coming unmixed from the liver. Similarly the duodenal drainage contained occasional traces of bile but frequently was water clear. The composite result depended on the resistance of the sphincter and the volume of secretion at various intervals.

When this drainage material was examined for amylase (Fig. 11) it was seen that the concentration of amylase was approximately equal in the biliary and the duodenal drainage. The

Figs. 12 and 13. Injection of iodized oil in this case in which amylase was recovered in the T tube drainage, revealed a moderately spastic sphincter and a dilated common bile duct (Fig. 12, left). The pancreatic duct (arrow) was visualized following the injection of morphine, only after two previous failures (Fig. 13).

Fig. 14. The optimum conditions for the production of pancreatic reflux. In this case (Table I and Figs. 2 and 3) the injection of secretin was followed by the appearance of amylase in low concentration in the bile samples only. Morphine stopped all reflux due to spasm of sphincter of Oddi and duodenal wall. Hydrochloric acid intraduodenally produced spasm only of the sphincter and resulted in a maximum reflux of pancreatic juice.

small differences being due to variable admixtures of bile.

However in most cases of pancreatic reflux, amylase was found in the biliary drainage quite infrequently and the pancreatic duct was visualized only after producing spasm of the sphincter of Oddi by means of morphine.

Fig. 5. The relative concentrations of amylase in the T tube drainage and in the duodenal drainage following spasm of the sphincter of Oddi produced by intraduodenal administration of hydrochloric acid (see Fig. 14). This indicates that about one third of the biliary drainage consisted of pancreatic juice.

In the following case (Figs. 12 and 13) the pancreatic duct was visualized by injection of iodized oil only after the third attempt, and amylase was found in the bile after six samples of bile were analyzed.

Accordingly the patient was given intravenously a standard dose (80 clinical units) of

Figs. 6 and 7. The optimum conditions for visualization of the pancreatic duct. Iodized oil was injected into the biliary tract in a patient who had been fasted, had all stomach contents aspirated by Levine tube suction for 4 hours previously and had received subcutaneous injection of $\frac{1}{8}$ grain morphine 1 hour previously—note complete filling of pancreatic duct (arrow). Slight rotation of the patient (Fig. 7 right) clearly reveals the anatomical relationship of the two ducts and their junction above the sphincter of Oddi.

secretin and the hilar drainage collected at 10, 20, 40, and 60 minute intervals (Fig. 14). Amylase was recovered only in the 10 and 20 minute samples. When morphine was given just before the injection of secretin, no amylase was recovered due to the fact that the spasm produced by the morphine involved not only the sphincter of Oddi but also the duodenal wall, shutting off any reflux. In a third procedure a duodenal tube was passed and following the injection of secretin intravenously 20 cubic centimeters of one-tenth normal hydrochloric acid was introduced intraduodenally every 10 minutes. This produced spasm of the sphincter but not of the duodenal wall and as can be seen a large amount of pancreatic juice (as represented by amylase) was recovered in the biliary drainage. The concentration of amylase recovered in the bile as compared to the concentration in the duodenal contents (Fig. 15) showed that one third of the hilar drainage consisted of pancreatic juice. There can be no question that such procedures which control both the flow of pancreatic juice and the resistance of the sphincter of Oddi will result in the discovery of the maximum incidence of pancreatic reflux.

Similar principles were applied in the visualization of the pancreatic duct by iodized oil. Since two main factors—food and hydrochloric acid, stimulate the secretion of pancreatic juice, the patient was fasted and a Levine tube was passed 2 hours prior to x-ray examination

for continuous suction of the stomach contents. To control the resistance of the sphincter of Oddi, morphine, $\frac{1}{8}$ grain, was given one hour prior to the cholangiographic study. As the kymographic tracing in Figure 3 demonstrates 1 hour after morphine injection the resistance of the sphincter falls almost invariably to about 200 millimeters of water. By this time the spastic effect of morphine on the duodenum has worn off. When iodized oil was injected into the common bile duct under such conditions the whole pancreatic duct was visualized (Figs. 16 and 17).

CONCLUSION

Therefore it can be seen that control of pancreatic secretion and control of the resistance of the sphincter of Oddi by various means can be utilized to diagnose pancreatic reflux after operation on the hilar tract. Similar methods are being developed now to diagnose this condition on the operating table.

THE EFFECT OF EARLY POSTOPERATIVE RISING ON THE RECURRENCE RATE OF HERNIA

JAMES B BLODGETT M.D., and EDWARD J BEATTIE, M.D., Boston, Massachusetts

THE original article on this subject was written by Ries, a gynecologist in Chicago in 1899. He was impressed by the rapid return of strength in the patients who rose early after operation and he noted the lack of unfavorable complications resulting from early rising. Although the practice of early postoperative rising was taken up by many of the European surgeons it was not widely used in this country until interest in the subject was stimulated by Leithauser of Detroit in 1941 when he published a series of 436 cases. Since the publication of Leithauser's first article there have appeared a number of clinical reports on early postoperative ambulation.

In June of 1942 a critical investigation of early postoperative rising was undertaken at the Peter Bent Brigham Hospital (1). This was to study what effect early ambulation has on postoperative complications, and whether it has any effect on the late operative results. Since postoperative complications are most common among patients having major intra-abdominal surgery this group was used to test the effect of early postoperative rising on postoperative complications. Two hundred and thirty-eight such patients who had risen on the first or second postoperative day were compared with 443 patients who got up after the seventh postoperative day. Our pertinent conclusions of that study were that the incidence of atelectasis was slightly lower in the early rising group (4.6% compared with 6.3%) and that the incidence of deep-leg vein thrombophlebitis however was slightly higher in the early rising group (2.9% compared with 1.8%). With respect to the incidence of postoperative wound disruption there was a slight reduction in the early rising group (1.3% against 2.7%).

From the Peter Bent Brigham Hospital, Surgical Service.

Presented in the forum on Fundamental Surgical Problems before The Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-30, 1946.

Today we present the results of a controlled study to determine the influence of early postoperative rising on the recurrence rate of hernia. The control group consists of 302 various herniorrhaphies on 177 patients. These patients got out of bed on the seventh to the fifteenth postoperative day. They were followed from 6 months to 7 years. The test group consists of 174 herniorrhaphies in 139 patients. The majority of the test group rose on or before the first postoperative day: 11 patients rose on the second day. They were all followed from 6 months to 4 years. Interrupted, fine silk technique was used in all cases of both groups.

The technique of getting the patient out of bed is essentially the same as Leithauser's. On the morning following operation the patient is turned on the side operated upon. He flexes his hips and knees so that his lower legs are at the edge of the bed. The nurse holds her elbow in the patient's elbow and the patient pushes his feet off the side of the bed as the nurse assists him up sideways to a sitting position. As the patient sits on the side of the bed slippers with heels, or shoes, are put on before he stands on the foot stool. While standing he is encouraged to breathe deeply and to cough several times. The patient then walks around the bed and sits in his chair for about 20 minutes. As he returns to bed, the walking and coughing are repeated. He is assisted out of bed in this manner twice daily until he can get up himself which in cases of herniorrhaphy is usually on or before, the third postoperative day. If the patient wishes to get out of bed on the day of the operation, he is allowed to do so unless there is some specific contraindication. Many of the patients who had had herniorrhaphy performed under local nerve-block anesthesia, got out of bed to eat lunch on the day of operation.

There was no selection among the patients who rose early following herniorrhaphy. The

TABLE I.—THE RECURRENCE RATE OF INDIRECT INGUINAL HERNIAE

Type of operation	Non-early risers		Early risers	
	Number	Recurrence	Number	Recurrence
Halssted	27	2	20	3
Bassini	85		7	
Other	Ferguson 1 McVay 1 Other		Ferguson 1 McVay 7 Orchiectomy 3 Others	
Totals	22	(3.6%)	24	(4.2%)

TABLE II.—THE RECURRENCE RATE OF DIRECT INGUINAL HERNIAE

Type of operation	Non-early risers		Early risers	
	Number	Recurrence	Number	Recurrence
Halssted	7	5	22	4
Bassini	28		20	
Others	McVay 1 Galle 1		McVay 3 Orchiectomy	
Totals	40	(6.2%)	30	(4.3%)

group includes older patients patients with poor abdominal wall structures, and patients who had all types of anesthesia and operative repairs.

As a group, the early risers were somewhat older because the younger patients were in the Army during the period when most of the early rising patients were operated upon. As we review the two groups we are again impressed by the rapid postoperative recovery which is found to be present among the group of early rising patients.

In comparing the recurrence rates in the two groups, the results are classified with respect to the method of operative repair¹ and the type of hernia, that is indirect direct femoral incisional and umbilical. Indirect inguinal hernia according to Watson's monograph, carries a recurrence rate of 5 to 10 per cent. Shelley in an exhaustive study of over 1600 indirect inguinal herniae at the New

¹The Halssted repair refers to Halssted's modified repair in which both the conjoined tendon and the external oblique fascia are sutured below the spermatic cord so that the cord is transplanted into the subcutaneous tissue and the external ring approximates the internal ring in position.

TABLE III.—THE RECURRENCES IN FEMORAL, INCISIONAL, AND UMBILICAL HERNIAE

Type of hernia	Non-early risers		Early risers	
	Number	Recurrence	Number	Recurrence
Femoral	8		6	
Incisional				
Umbilical	3		7	

TABLE IV.—TOTAL RECURRENCE RATE OF INGUINAL HERNIAE

Type of hernia	Non-early risers			Early risers		
	Number	Recurrence	Per cent	Number	Recurrence	Per cent
Indirect	22	5	22.7	24	5	20.8
Direct	40	6	15.0	30	4	13.3
Totals	180	11	6.1	50	9	18.0

York St. Luke's Hospital found a recurrence rate of 7.2 per cent.

Table I gives a tabulation of the recurrences in indirect inguinal herniae. It shows that in the non-early rising group there were 5 recurrences in 131 operations and that in the early rising group there were 5 recurrences in 114 operations. This is a recurrence rate of 3.8 per cent in the non-early risers and 4.3 per cent in the early risers.

For direct hernia, Watson gives the recurrence rate as between 10 and 20 per cent. It may even be higher. As recently as 1942 Page reported a recurrence rate for direct hernia of 35 per cent.

Table II presents a tabulation of the recurrences for direct inguinal herniae which shows that, in the non-early rising group there were 6 recurrences in 49 repairs. In the early rising group there were 4 recurrences among 36 repairs. This is a recurrence rate of 12.2 per cent in the non-early risers and 11.1 per cent in the early risers.

The recurrences in the few femoral incisional and umbilical herniae are listed in Table III. This shows no appreciable increase in recurrences in this small group as a result of early rising.

Table IV gives the total recurrence rate in inguinal hernia. It is seen that the recurrence rate in 180 inguinal herniorrhaphies treated

by postoperative bed rest is 6.1 per cent whereas, the recurrence rate in 150 inguinal herniorrhaphies treated by early rising is 6.0 per cent.

CONCLUSION

We conclude from these data, that early postoperative rising exerts no significant effect on the recurrence rate of hernia.

THE USE OF THE MALE SEX HORMONE IN WOMEN WITH BREAST CANCER

FRANK E. ADAIR, M.D. F.A.C.S. New York, New York

WE have now arrived at the point where it has become profitable to pursue the use of hormone therapy in certain types of human cancer. Huggins made one of the most important contributions that have been made in many years in the field of cancer when he was able to produce 25 per cent cures in prostatic cancer—a disease widely recognized to have an extremely high mortality. His study of the hormone influence in this disease naturally suggested exploration of other fields where cancer is either produced or materially influenced by the sex hormones. Beside the prostate it is patent that other organs such as the breast, uterus, ovaries, adrenal testes and thyroid should each receive serious attention and experimentation.

I recently made a study of 5000 cases of early breast cancer relative to their ages at the time of the development of their cancer.

The peak of the greatest number developing cancer was 45 years. This age probably represents the time when certain chemical changes are present deviating somewhat from the normal ovarian hormone. The ovaries are undergoing at this age certain changes leading up to the menopause which comes on at an average of 46½ years.

On the other hand the year when next to the greatest number develop breast cancer is age 60 years and here we probably have a patient who has practically no ovarian hormone output. It is possible that the 13 or 14 years since having a definite ovarian function as evidenced by menstruation may represent a complete lack of ovarian hormone output and may represent a possible cause for the production of breast cancer in the older age group. This theory fits well into the fact that

the women of 60 years and older with breast cancer are improved by the use of the estrogens.

During the past several years my department has been making a clinical experimental study on approximately 200 cases of cancer of the female breast in which testosterone propionate has been employed.

In the beginning the results of this therapy when using small amounts seemed to be of no value (Farrow and Woodward). I next treated 48 patients in my private practice employing a daily dose of 25 milligrams intramuscularly to each patient (175 mgm weekly). It soon became obvious that in certain cases of advanced breast cancer and more particularly in those metastatic to bone, that we were dealing with a very potent agent capable of producing striking clinical improvements as well as changes some of which were demonstrable by x ray films.

Up to this time we had been hampered in our clinical research by the high cost of testosterone propionate, and at this juncture Dr. Henderson of the Schering Corporation generously made it possible for us to commence our new attack employing large doses.

Dr. Julian Herrmann and I then began by giving some patients as much as 100 milligrams daily by intramuscular injections of the agent in oil. We varied the dose using in some instances the testosterone pellets placed subcutaneously in order to obtain a more prolonged absorption of the agent. After much trial and error we arrived at our present dose of 100 milligrams by intramuscular injection three times weekly for a period of 8 to 10 weeks making a total dosage of 2400 to 3000 milligrams. We freely admit that we have not come to a final conclusion as to what should be the exact dose, how much total should be delivered and how long it should be continued. Obviously many of these factors must be determined and will be influenced by whether or not the patient

The studies were made possible by a grant from Mr. Louis Marx to the Breast Service of the Memorial Hospital, New York. Presented in the symposium on Cancer before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

still menstruates, on whether or not her ovaries have been made functionless by x ray or surgical castration as well as many other factors.

At the present time the work is being pursued by my associates and myself not only to the advanced cases but also in the new cases of early operable breast cancer.

It has now gotten almost beyond the point where it is necessary to demonstrate the value of testosterone therapy by giving case reports as we have already placed ample cases in the literature which show the value. We are now at the point where we can draw general conclusions of what may be anticipated by this therapy.

Our experience has shown that in only a small percentage of cases is improvement to be anticipated when the cancer involves the soft tissues such as liver, lungs, brain and local skin recurrence. It is true that in a few instances there have been striking improvements where advanced ulcerating breast cancer with surrounding skin nodules axillary nodes and neck nodes were involved where masses were metastatic to the lungs and in one instance where the patient was having convulsions from metastatic disease in the brain. However I fear it must at present be taken for granted that most such cases receive no benefit aside from the temporary general improvement which frequently comes as a result of testosterone injections.

On the other hand a most striking improvement is obtained in most of those cases having bone metastasis. There is some specificity or predilection for the agent to do its work of repair in the bone cases—and as yet we do not understand the reason. It is probable in the metabolism of bone repair under the influence of testosterone that the billions of cancer cells are 'snowed under' by the copious deposit of calcium precipitates especially in areas of bone destruction—a locking in process where cell reproduction is difficult. Similar to prostate cases, the cancer cells will still be present after testosterone therapy. We do not yet know whether the improvement of the bone destruction by the invading cancer is confined to cases of breast cancer alone or whether metastasis to bone from some other

type of cancer may also be improved by testosterone such as from thyroid or ovaries. It is important that this study be pursued and that a study in cases of primary bone sarcoma also be carried out.

After approximately 2 weeks of testosterone therapy the relief of pain from bone metastasis is usually very real. Lack of sleep due to pain is replaced by a natural sleep. It is usually possible to cease giving narcotics which may have been given in large amounts. Some of our patients who had such pain that it was not possible to continue their work, were able to return to their jobs in comfort by the end of a month of therapy. The areas of bone destruction as evidenced by absorption of the calcium salts by collapse of vertebrae, and by fracture of ribs are filled in with dense callus similar to that seen following x ray therapy. How long this improvement in the osseous tissue persists is not yet known. However we have 3 cases in which disease was confined to bone having no ascertainable soft tissue involvement living free of evidence of disease or symptoms for a period of $1\frac{1}{2}$ to 2 years after commencing the testosterone therapy.

A brief example of one of these cases was a woman aged 71 years who had been confined to her bed for a period of 10 months, with widespread bony metastases to the spine, pelvis and ribs several of the latter being fractured. After 4 weeks of testosterone therapy she was able to leave her bed. At the end of 3 weeks of therapy she developed as is so common the feeling of elation and well being. By the end of 6 weeks she was walking all over the city free from symptoms. The only symptom which bothered her was the annoyance and the irritation of the enlarged clitoris. This patient started on her testosterone therapy in July 1944 and up until December 1, 1946 a period of 2 years 4 months, was living in good health. Three weeks ago she began to have nausea which has persisted, and it may be suspected although not demonstrable that she may have metastases to the liver or to the abdominal lymph nodes. It is not unusual for a patient with metastasis to bone to keep the disease confined there for some time before finally spilling over into soft tissues such as the lungs or abdomen.

Fig. 1. Demonstrating destruction of a large area of frontal bone by metastatic cancer from breast.

In cases of widespread bony metastasis the use of testosterone propionate seems more efficacious longer lasting and more practical than x ray therapy. When it becomes necessary to treat multiple widespread areas of metastatic bone disease, with the x rays it becomes a matter of great difficulty to deliver so many doses over so many areas not only because of the nausea which frequently accompanies such treatments but there is also the practical problem of bringing a patient who suffers intensely from bone metastasis to the hospital or x ray laboratory furthermore such a large number of x ray treatments may produce an anemia in the face of which x ray therapy itself becomes ineffective.

We have had many instances in which the skin of the patient had been so damaged by x ray therapy that it was not possible or practical to deliver further x ray treatments to the bones. Fortunately it is usually possible in such a case to commence with the testosterone therapy and still obtain some degree of clinical improvement.

Fig. 2. The same patient 10 weeks later following 24 injections, 100 milligrams each, of testosterone propionate, totalling 2400 milligrams. The area of destruction has been filled in by callus and the mass protruding from the forehead has disappeared.

In the advanced cases of bone metastasis the blood chemistry is fairly consistent. As a rule such a patient has a blood calcium well above the normal of 10 to 12 milligrams per 100 cubic centimeters. The blood calcium at times goes up as high as 17 milligrams. Under testosterone propionate therapy the rule is that the blood calcium slowly comes back into normal limits theoretically being redeposited in the areas of bone destruction.

The alkaline phosphatase also acts characteristically, it is an enzyme necessary for bone repair. The normal limits are 3 to 5 milligrams. During bone repair under testosterone this figure at times reaches as high as 15 milligrams indicating that bone repair is taking place.

Most of our work to date has been on advanced breast cancer cases. However we have recently started to work on the early operable cases of breast cancer using the radical mastectomy supplemented by large doses of testosterone implanted into the latissimus

dorsal muscle or into the subcutaneous tissues near the wound at the time of the operation. Although we have used this combination in 135 such cases to date we have nothing to report as yet. Two months after the operation we will again implant further doses of testosterone on the theory that possibly recurrence and metastasis may be influenced or lessened by subjecting any remaining cancer tissue to the unhealthy environment of testosterone bearing blood and serum. It is obvious that such a human experiment should be undertaken and evaluated.

It may be of some interest to note that in two pregnant patients with breast cancer receiving testosterone that repeated Aschheim-Zondek tests were negative up to 5 months of pregnancy when the patients could feel life.

It is scarcely necessary to state that the patient receiving testosterone therapy develops unpleasant masculinizing sequelae as evidenced by a deeper husky voice hair on the

face, pimples on the face and body and an enlarged clitoris which in certain cases becomes a source of great annoyance.

On the other hand under testosterone therapy there is usually at least temporarily a gain in weight, a feeling of well being, a loss of bone pain and a repair of the bone destruction caused by the metastatic disease.

As a rule the *clinical* improvements by the use of testosterone are far more striking than the x ray improvements reveal.

Testosterone may be employed on female patients with breast cancer at any age, while the estrogen therapy must be strictly confined to patients of 60 years and older.

It must be here emphasized that we are not stating that testosterone is a cure for breast cancer however its effects are very profound and gratifying but indicate that much more clinical research must be carried out in this field before we can fully evaluate dosage or final results.

RESECTION OF INTRA-ABDOMINAL CANCER THAT HAS INVADDED THE ANTERIOR ABDOMINAL WALL

ALEXANDER BRUNSCHWIG MD F.A.C.S Chicago Illinois

INVASION of the anterior wall by carcinomas primary in the abdominal viscera or invasion of the anterior abdominal wall by metastases from such growths does not constitute a situation in which radical surgical excision is necessarily contraindicated. The primary growth together with its parietal extensions may be excised *en masse* to removal in some instances of all macroscopic evidence of tumor. Such procedures were carried out in a limited group of patients the histories are briefly as follows:

CASE 1 J C no 283119, male aged 66 years was subjected to a right hemicolectomy resection of the lower half of the stomach and elliptical portion of the abdominal wall about the umbilicus to remove a large carcinoma of the transverse colon which was spreading to the adjacent structures mentioned. Patient is living and well 4 years and 5 months after operation.

CASE 2 G P no 332661 male aged 63 years, had a resection *en masse* of 16 centimeters of sigmoid

colon an elliptical segment of the parietal peritoneum and deep fascia in the left lower quadrant and segment of the lower jejunum 10 centimeters in length for carcinoma of the sigmoid which was infiltrating the jejunum and anterior abdominal wall. End-to-end enterostomy and double barrel colostomy were performed and the latter was subsequently closed. Patient is living and well 2 years 5 months after operation.

CASE 3 Jaw no 274690, female aged 34 years. Laparotomy was performed for removal of many peritoneal metastases from a pseudomucinous cyst—adenocarcinoma of the right ovary in 1941. A second laparotomy was done for resection of numerous metastases over the peritoneal surfaces of bowels and in the mesentery of the small intestine. A half fist size mass infiltrating the abdominal wall in the right lower quadrant was excised together with portions of the rectus muscle. Patient is living and well 2 years 2 months after second operation.

CASE 4 J L no 322684 male aged 39 years. Resection of the abdominal wall of the left upper quadrant and subjacent recurrent colon for carcinoma with descending colon spleen containing 4 metastases and tail of pancreas. Double-barrel colostomy was done and was later subsequently closed. Patient is living 1 year 2 months after operation. He has an enlarged nodular liver due to metastases.

CASE 5 P W no 379472 male aged 58 years. A right hemicolectomy was done and 20 centimeters of

From the Department of Surgery, University of Chicago. These studies were aided by the Chas. H. and Mary F. S. Worcester Fund, University of Chicago.

Presented in the symposium on Cancer before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

Fig. 1. Diagrammatic representation of operations performed in Cases 1 to 3. Black areas indicate carcinoma.

shaded areas indicate extent of anterior abdominal wall involved by neoplasm and resected.

Fig. 2. Diagrammatic representation of operations performed in Cases 4 to 12. Black areas indicate carcinoma,

shaded areas indicate extent of anterior abdominal wall involved by neoplasm and resected.

the lower ileum was resected *en masse* with the abdominal wall of the right lower quadrant for carcinoma primary in the cecum and infiltrating the ab-

dominal wall. Ileo transverse colostomy was made. This patient is living and well 5 months after operation.

Fig 3. Photograph of surgical specimen from Case 5 showing A large segment of lower right quadrant of abdominal wall including skin, subcutaneous fat and musculature infiltrated by C underlying carcinoma arising in cecum, B ascending and transverse colon, I lower ileum.

CASE 6 P. H. E. no 319547 male aged 49 years. An exteriorization excision was done of the sigmoid bearing carcinoma, together with a long loop of the upper ileum invaded by carcinoma, as well as the mesentery of the ileal loop, the dome of the urinary bladder and the deeper portion of the anterior abdominal wall in the left lower quadrant. The colostomy was subsequently closed. Patient lived 14 months returned to work for 8 months, but died of recurrences.

CASE 7 E. R. no 160578 female aged 48 years. An elliptical incision 11 by 7 centimeters was made in the left lower abdominal wall to include the mass of recurrent colon carcinoma (previous Mikulicz resection for primary growth) and the involved sub-jacent descending colon. A double barrel colostomy was made. Patient lived 10 months then died of recurrences.

CASE 8 C. P. no 325186, female, aged 55 years. Resection was done of the lower two thirds of the stomach, body of pancreas, spleen, periumbilical region of the abdominal wall, the falciform ligament for carcinoma primary in the body of the pancreas, with local spread and metastases to structures mentioned. Patient lived 4 months. She died of carcinomatosis.

CASE 9 E. L. no 350135 female, aged 68 years. Resection *en masse* was done of previous lower right rectus incision scar with underlying mass infiltrating abdominal wall. Multiple small metastatic masses over the peritoneum also were excised. Patient lived 4 months received palliation.

CASE 10 Gomol no 306534 female, aged 52 years. June, 1943 a suprascervical hysterectomy and salpingo-oophorectomy for bilateral cyst-adenocarcinoma of ovaries were done. October 1943 the peri-

umbilical region of abdominal wall *en masse* with underlying and attached tumor 15 centimeters in diameter was excised. The latter was a large metastatic mass, the site of extreme pain. Patient survived 2 months. She died of carcinomatosis.

CASE 11 E. B. no 339809 male aged 28 years. Operation was carried out as follows: total gastrectomy partial hepatectomy partial pancreatectomy transverse colectomy splenectomy resection *en masse* with the above, of the abdominal wall in the left upper quadrant for round cell sarcoma (radio-resistant). Patient survived 3 months died of rapidly developing sarcomatosis.

CASE 12 C. B. no 255457 male aged 48 years. Resection *en masse* was carried out of cecum ascending colon right kidney and ureter 70 centimeters of ileum and abdominal wall in the right lower quadrant for recurrent carcinoma of the cecum.

TABLE I.—SUMMARY OF RESULTS

Case 1	Living and well	4 yrs. 5 mos.
Case 2	Living and well	2 yrs. 5 mos.
Case 3	Living and well	2 yrs. 2 mos.
Case 4	Living but has hepatic metastases	1 yr. 2 mos.
Case 5	Living and well	5 mos.
Case 6	Lived	1 yr. 2 mos.
Case 7	Lived	10 mos.
Case 8	Lived	4 mos.
Case 9	Lived	4 mos.
Case 10	Lived	2 mos.
Case 11	Lived	3 mos.
Case 12	Lived	12 days
Case 13	Lived	5 days†
Operative Mortality—2 Patients		15.4%

*Death from coronary occlusion.

†Peritonitis.

Patient died twelfth day postoperative. Necropsy revealed coronary occlusion.

CASE 13 C F no 307424, male, aged 77 years. Exteriorization resection was done of the descending colon and the musculature of the left flank for carcinoma of the former invading abdominal wall musculature with abscess formation

DISCUSSION

In all instances it was possible to close the wounds tightly following resection of portions of the abdominal wall. There were no wound disruptions. Soft rubber drains were inserted in some cases when suppuration associated with the parietal invasion was obvious. No definite recommendation may be made for these repairs since each procedure represents a special situation. The generally accepted principles of fashioning full thickness (skin, fascia, and sometimes muscle) sliding flaps are followed.

Three patients have survived over 1 year and are living well, and returned to their usual occupations for an average of 36 months since operation. One patient, Case 4, received palliation for a year, having returned to his usual occupation but at this writing exhibits deterioration due to obvious multiple hepatic metastases.

The results in the series of 13 patients are summarized in Table I. One patient survived 1 year and 2 months, dying of metastases, but had returned to work for a period of 8 months. One is living and apparently well 5 months after operation. The patients who survived for shorter periods appeared to have received palliation although this was brief. Operation was performed in these patients because of pain and obstructive symptoms referable to the mass that was excised together with its parietal extensions. Some of the best results were achieved in patients with cancer of the colon which had invaded the abdominal wall. It has long been recognized that such carcinomas may evolve by local spread to adjacent tissues and viscera before distant metastases occur and these results are in accordance with this principle.

SUMMARY

Invasion of the anterior abdominal wall by carcinoma primary in an abdominal viscus does not necessarily indicate that the lesion is inoperable. Palliation and prolonged survival of the patient may follow extensive resections of such neoplasms with their parietal involvements.

OBSERVATIONS ON THE GENETIC NATURE OF GASTRIC CANCER IN MICE

LEONELL C STRONG Ph D., Sc.D New Haven, Connecticut

THE practice and science of medicine being based exclusively or even predominantly upon the science of bacteriology the conclusion is inevitable to some investigators that a cell or an individual is incapable of doing anything without being impinged upon by some external force. The science of genetics, stemming from the study of embryology teaches differently. Genetics teaches that a zygote that is the fertilized egg when placed in a suitable environment of temperature and humidity, given a few specific chemical entities such as the essential amino acids and the vitamins and a source of energy is capable by development from spatially related internal nuclear entities or genes of giving rise to an adult plant or animal. This determination is so precise that many racial, familial, and individual characteristics are handed down from one generation to the next. This process of heredity has undoubtedly been going on from immemorial time and it probably will go on in the future subject to change only by the sporadic appearance of mutations from time to time. It is the present intention to see whether this concept of biologic determination can also be applied to cancer particularly to cancer of gastric origin.

In the first place all cells of the body are derived by cell division from the zygote. Since cells and tissues reproduce physiological and morphological characteristics of their species in each and every generation they must, of necessity retain many potentialities from their zygotic origin. Superimposed upon this background of intrinsic determinations are many variations necessitated by environmental changes which are not of necessity hereditary. Now cancer is derived by cell division from some somatic tissue and therefore must

retain some potentialities derived from the zygote.

The production of gastric carcinoma in mice was the result of the practical application of genetic principles by which the attempt was made to duplicate or to simulate in mice the variable biological state of the human population. For this purpose the genetic processes of hybridization and selection were used. In addition however each mouse received the subcutaneous injection of 1 milligram of methylcholanthrene dissolved in 0.1 cubic centimeter of sesame oil at 60 days of age. This procedure of injection has been followed for both parents for many generations. Beginning with the early hybrid generations the tendency to give rise to local tumors at the site of the injection of the carcinogen has been suppressed by keeping the descendants of the most resistant to cancer pair of mice in each generation. Due almost exclusively to this regimen of selection toward resistance to induced cancer there has been produced an increased latent period for the appearance of not only locally expected tumors but also of other types of tumors which appeared due no doubt to the fact that the selected hybrid mice with increased biologic variability lived longer than they normally would following the injection of methylcholanthrene. Four stages or classes of mice based upon the classification of induced tumors have appeared in this selection experiment as follows: (1) the appearance of tumors such as epidermoid carcinoma and fibrosarcoma at the site of injection of the carcinogen; (2) the surface spread of tumors over the entire body such as carcinoma of the mouth, the rectum, etc.; (3) the appearance of tumors in the thoracic cavity such as adenocarcinoma of the lung, bronchiogenic carcinoma and mesothelioma; and (4) the occurrence of tumors appearing in the abdomen such as primary carcinoma of the liver, liposarcoma of the uterine mesentery, leiomyosarcoma of the uterus and gastric

This experiment has been made possible by grants from The Jane Coffin Childs Memorial Fund for Medical Research and The Anna Fuller Fund. Presented at the symposium on Cancer before the Clinical Congress of The American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

carcinoma. Beyond these four stages where specific types of tumors occurred there was obtained a period, of short duration in which no tumors appeared in spite of the fact that an overwhelming dose of a very powerful carcinogen had been injected. Even with continued selection toward greater resistance to all types of induced tumors, there occurred a reversal of susceptibility to induced cancer in which tumors appeared earlier and earlier in the succeeding selected generations. For the present purpose however we shall confine ourselves to the gastric carcinomas which began to appear in stage 4 enumerated above. These gastric lesions showed histological variability some growing as polyps, while others grew invasively through the underlying muscular layers of the stomach. Metastases into the surrounding viscera have also been obtained from these adenocarcinomas of gastric origin. When a suitable genetic experiment had been performed, it was demonstrated that the susceptibility to give rise to this gastric lesion showed linkage relationship with the gene that underlies brown hair pigmentation. Thus it is clear that a mutation has occurred on the brown chromosome sometime during the extent of the injection of methylcholanthrene into mice and that this mutation is responsible in part, for the development of gastric carcinoma following the subcutaneous injection of methylcholanthrene. Another point of genetic interest is the fact that the untreated descendants of these mice which had developed gastric carcinoma following the subcutaneous injection of methylcholanthrene continued to develop gastric carcinoma spontaneously and they have continued to do so through eight untreated generations. At periodic times during the experiment of injecting both parents at sixty days of age with methylcholanthrene a group of 120 mice have been separated off and kept under standard laboratory conditions without being subjected to any experimental procedure. In the succeeding groups of 120 mice referred to above the incidence of spontaneous gastric lesions and carcinomas increased in frequency and, at the same time appeared earlier and earlier in life. Now there is available a strain of mice in which all individuals develop gastric lesions or carcinomas

or some closely related biological entity spontaneously, the males, however showing a greater susceptibility to gastric lesions than do females.

In addition to these gastric lesions of immoal origin there has also been obtained several adenocarcinomas and squamous carcinomas of the forestomach which may serve as a source of material for other types of neoplasia induced by a subcutaneous injection of methylcholanthrene. In the gastric lesion, some of which are undoubtedly adenocarcinomas, it is clear that we have produced a hereditary disease or an inherited susceptibility to a disease by chemical means.

In his very excellent book on the "Foundations of Zoology" Professor W. K. Brooks had this to say "If like Paley I kick a stone I may change its position, raise its temperature, and bring about other changes that might all be computed from a few simple data. What happens if instead of a stone, I kick a dog? What a difference between a kick against a dog and one against a stone! In one case the simple conditions may be stated in a few words, and the result may be computed while in the other, a book would not suffice for the statement of all the facts, and the best science of our day is powerless to compute the result." This illustration is used to discuss the theme of the entire book of the relation of stimulus to intrinsic constitution in biologic response or behavior. Perhaps it is not too far fetched to apply this concept to cellular physiology especially to cancer. One may insult a cell by a multiplicity of agents such as bacteria, viruses, hormones and vitamins, but, in the last analysis, how the cell responds or even acts or fails to respond, is due to no small degree to its intrinsic genetic constitution determined, in part by its origin from the zygote. It is this genetic concept of the nature of intrinsic biologic variability together with chemical induction, that is making possible the development of many benign and malignant tumors in mice. A concept to be of value should not only explain the contributions of the past, but should pave the way for new contributions. It is not out of place to point out to an assembly of surgeons that the cancer problem has not been solved and therefore we should not expect to find the

solution in the literature. Rather should it be desirable to advance in the study of cancer by producing more and more malignant conditions in experimental animals that duplicate or even approach the types of tumors that are killing more and more men and women at an ever increasing rate. For this purpose the genetic concept of cancer has justified itself and

should be of more than an academic interest. In conclusion it may be pointed out that if genetic principles of hybridization, selection and inbreeding are capable of giving rise to a great multiplicity of tumor types then the reverse of these same genetic principles should lead to the building up of a biologic state that will refuse to give rise to cancer in any form.

CORRELATION OF THE USE OF ANTIBIOTIC AND CHEMOTHERAPEUTIC AGENTS WITH GENERAL PRINCIPLES OF SURGERY

CHAMP LYONS M.D. New Orleans, Louisiana

THE introduction of potent chemotherapeutic and antibiotic agents challenged many traditional concepts in the surgical management of infections. A new group of nonsurgical specialists has arisen from the ranks of internists to concern themselves with the drug treatment of infections previously considered as surgical diseases. Paradoxically this trend has not been correlated with a diminishing surgical responsibility for the treatment of impending or established infections. In fact the net impact of this challenge has been the visualization of new fields for surgical exploitation. Entirely apart from the generally acknowledged necessity for the surgical drainage of pus there are four major problems of clinical concern: (1) treatment of impending wound infection, (2) treatment of mixed infections due to both gram-positive and gram-negative bacteria, (3) treatment of the intravascular complications of bacteremic infections, and (4) rôle of anti-bacterial agents in surgical management.

It is interesting that the dramatic accomplishments of the era of antibacterial therapy have so little altered the integrity of estab-

lished and fundamental principles of surgery. Controversy has attended problems requiring surgical judgment, but control of the capricious quality of bacterial invasiveness has made more clearly evident the violation of fundamental biologic laws. The broad diagnosis of infection can no longer absolve errors in diagnosis, judgment or technique. It is the purpose of this discussion to summarize the basic surgical principles validating this viewpoint.

TREATMENT OF IMPENDING WOUND INFECTION

Experience in wound management among military surgeons in World War II crystallized much opinion about matters apparently still controversial among civilian and experimental surgeons. The major point at issue is the logic of local chemotherapy. Military experience justifies the abandonment of local chemotherapy in all wounds except occasional complicated wounds of serous cavities or major joints. Included in this philosophy of wound management is abandonment of the concept of prophylactic use of chemotherapeutic and antibiotic agents. Prevention of infection is an exercise in surgical technique. Antibacterial agents are reserved for the treatment of impending infection upon indications derived from clinical appraisal of the wound. Thus, chemotherapy is solely an adjuvant to surgical competency in wound management.

From the Department of Surgery, Tulane University School of Medicine and the Department of Surgery, Ochsner Clinic. Presented in the symposium on Antibiotic and Chemotherapeutic Agents in Surgery before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-10, 1946.

Wound infection may be subdivided into two major components: invasive infection and wound suppuration. The invasive bacteria, capable of destroying living tissue, are the hemolytic streptococcus, toxigenic clostridium and staphylococcus. All are susceptible to penicillin therapy with occasional strain exceptions. Wound pathogens, responsible for wound suppuration, are a more heterogeneous group and relatively resistant to currently available chemotherapy. In addition the wound pathogens demand a nutritional pabulum other than living tissue within the wound. Devitalized tissue, blood clot and serous exudate in an open wound are removed naturally by septic decomposition; hence, the existence of such a pabulum is of greater clinical importance than the identity of the bacteria concerned with its liquefaction. The initial surgical care of the wound and the use of splints and pressure dressings are far more practical than attempts to sterilize residual dead tissue or exudate within the wound. In other words, the surgically clean wound requires no local chemotherapy and no amount of chemotherapy can sterilize an imperfectly debrided wound.

The living tissues of the wound are best protected from the ever present hazard of invasive infection by perfusion with a blood-borne antibacterial drug. Systemic therapy achieves this objective. It has been learned that the surgically clean soft part wound risks invasive infection only by the hemolytic streptococcus and that sulfonamide therapy adequately anticipates this danger. However, residual blood clot has been found as potentially acceptable as dead muscle as a nidus for clostridium infection. The greater antibacterial potency of penicillin for clostridium and staphylococcus makes it the drug of choice for wounds with residual hematoma or devitalized tissue. Such wounds are the complicated soft part wounds and compound fractures.

Again clinical expediency has dictated the abandonment of routine bacteriologic culture of wounds as an index of infection. The gross pathologic appearance of the wound 3 to 10 days after initial surgical treatment is the best evidence of the adequacy of the initial excision and the presence or absence of infection. It is

this general principle which underlies the two-stage technique of wound management. A further development of importance is the segregation of reparative and reconstructive phases of wound management. Postponement of reconstructive procedures to an elective schedule during convalescence and after wound healing has yielded greater success in ultimate rehabilitation.

TREATMENT OF MIXED INFECTIONS DUE TO BOTH GRAM POSITIVE AND GRAM NEGATIVE BACTERIA

Evidence for the minor rôle as wound pathogens of the gram-negative bacilli of the coliform group is gradually appearing. Even in peritonitis and bronchopulmonary suppuration, penicillin appears to be optimally effective when used in dosage adequate to control the gram-positive components of the infection. A similar conclusion has been reached in the study of wound infections.

This reasoning does not extend, however, to infections of the urine, bile or cerebrospinal fluid. These body secretions contain an abundance of essential metabolites for bacterial growth and are deficient in sulfonamide inhibitors. Under the circumstances of wound infection of the urinary, biliary or cerebrospinal system, the combination of penicillin and either sulfonamide or streptomycin may be desirable. To be effective, chemotherapy must be combined with restoration of normal flow for these systems.

TREATMENT OF THE INTRAVASCULAR COMPLICATIONS OF BACTERIEMIC INFECTIONS

The reduced mortality rate in bacteremic infections offers the most convincing proof of the potency of presently available antibacterial agents. A consequence of this improved survival rate is an increasing incidence of residual complications of previously infrequent occurrence. Many unusual abscesses, such as the gas abscess of the retroperitoneal space as a complication of gas gangrene of the thigh, have been noted. Such abscesses rarely present problems in diagnosis or management. However, there are certain residual lesions of the vascular bed which are important for recognition and merit discussion as to principles

of treatment. These may be considered in two major categories: first the intravascular foci of suppuration and, second, the metastases therefrom.

The intravascular foci of suppuration may be surgically accessible or surgically inaccessible. That surgical excision of all septic thrombi is not mandatory may be deduced from the experience with endocarditis and cavernous sinus thrombophlebitis. That conservative management is not uniformly successful is apparent from the experience with pyelophlebitis. In the treatment of these lesions it is important to record the gradual abandonment of concomitant anticoagulant therapy in consequence of hemorrhagic complications.

The septic thrombi amenable to surgical attack are those associated with endophlebitis of the peripheral veins. Most frequently involved are the veins of the pelvic, jugular and saphenofemoral systems. The essential pathologic changes of septic endophlebitis render unlikely the detachment of a sufficiently large embolus to produce immediately fatal pulmonary infarction. Most commonly progressive septic infarction of the lung and subsequent focal pneumonitis result. More rarely there is an *extending thrombosis of a major venous trunk*. Such a process in the inferior vena cava with ultimate occlusion of the renal veins is associated with renal shut down and death from uremia. The life endangering qualities of these complications justify surgical intervention for any accessible focus of septic endophlebitis.

The possibility of septic endophlebitis is suggested by recurrent chills, spiking fever and persistent leucocytosis. The early diagnosis of pyrogenic thrombosis or septic pulmonary infarction is not always easy. The septic emboli in the lung are usually microscopically small and cast no shadow in the roentgenogram. The characteristic radiologic evidence of multiple rounded areas of slightly increased density is dependent upon the development of pneumonitis around the areas of infarction. It is characteristic of these lesions that they progress to suppuration in spite of intensive chemotherapy. Tension pneumothorax, pyopneumothorax, empyema and abscess formation are features of this suppurative

phase demanding appropriate consideration and treatment. Although the ultimate healing of multiple pyrogenic abscesses of the lung is remarkably complete in the survivors, early venous interruption is the preferred method of treatment. Local tenderness over a likely venous pathway may be the only clue to the particular site of venous involvement. More rarely, the differential diagnosis of septic endophlebitis and endocarditis of the right side of the heart may require consideration.

Ascending septic thrombophlebitis of the inferior vena cava is usually a complication of an obvious focus of inflammation or abscess of the pelvis or lower extremity. The clue to caval extension of the septic thrombus is massive edema of the extremity at the time of iliac involvement.

As a general principle it may be stated that excision of the affected segment is preferable to proximal ligation. Suppuration of the distal stump such as occurs spontaneously in the veins of the face may demand venotomy for drainage of pus. On the other hand technical considerations dictate simple ligation of the inferior vena cava. This is readily accomplished through a right-sided retroperitoneal approach unless the necessity for concomitant interruption of the ovarian veins dictates a transperitoneal approach.

Another complication and a little emphasized feature of the successful treatment of endocarditis of the left side of the heart is the occurrence of mycotic aneurysms. Early diagnosis of these lesions is mandatory if surgical treatment is to be successful. No method of aneurysmorrhaphy is applicable to the septic and necrotic wall of these aneurysms. The only practical method of treatment is proximal ligation. Fortunately many of these patients are sufficiently youthful so that adequate collateral circulation will develop after such an arterial interruption.

ROLE OF A THIRACETRIAL AGENT IN THE OVERALL PROGRAM OF CLINICAL MANAGEMENT

The technically ill patient depleted by persistent infection can rarely be cured by chemotherapy alone. This has been especially emphasized by the experience with actinomycetosis where the recurrent abscesses are not cured by

PHYSIOLOGIC ASPECTS OF SURGICAL INFECTIONS

JOHN S LOCKWOOD M D Med. Sc. D New York, New York

THE direct attack on the bacteria involved in surgical infections has been increasingly effective during the past 10 years. Scarcely a year has elapsed without bringing forth a new chemotherapeutic weapon better for some bacteriological purpose than those hitherto available. However there is ample evidence to indicate that the proper management of infections calls for much more than the ritualistic administration of the right drug for the right organism. It seems appropriate in this symposium to recall attention to three primary reservations which should temper the purely bacteriological approach in the management of surgical infections (1) Chemotherapeutic agents and antiseptics are only useful when they aid rather than interfere with the natural defense and recovery mechanisms of the body in infection the process which Fleming calls 'physiological antiseptics' (2) Effective management of many wounds infested with bacteria requires correction of an unhealthy physiological condition rather than a direct attack on the bacteria (3) In severe infections of almost all types there usually occur profound toxic functional derangements of organs and systems not immediately involved in the infectious process and the chemotherapeutic agents administered will not of themselves serve to remedy the consequences of such disorders.

It is the purpose of this paper briefly to discuss these three aspects of surgical infections and to indicate that the use of our new found weapons against bacteria must be handled with an understanding of their limitations so that we may at all times recognize the ultimate importance of guarding and implementing the physiological mechanisms of recovery from infection whether the infection be in a wound or a systemic invasive infection. The

principles to be discussed are by no means new in fact some of them were clearly recognized long before the discovery of the sulfonamides and penicillin. First will be considered some of the physiological aspects of treatment of localized tissue infections, or infected wounds, and next will be taken up the subject of toxemia in infection.

Sir Alexander Fleming writing of the investigations on wounds during World War I, performed by himself and other members of a research team led by Sir Almroth Wright, made the following significant statement "In view of the observations I have made, and which are quoted above I venture to suggest that the antiseptics at present in use will only exercise a beneficial effect in a septic wound if they possess the property of stimulating or conserving the natural defensive mechanism of the body against infection. If such a thesis be true, then it brings the antiseptic and the physiological treatments on to the same basis and it also makes it necessary in the estimation of the value of an antiseptic, to study its effect on the tissues more than its effect on the bacteria.

The evidence in support of these assertions was largely drawn from a series of laboratory experiments on wounds *in vivo* or on wound exudate *in vitro* with conditions which simulated as closely as possible the actual conditions existing in the wound. It was demonstrated that the ability of bacteria to multiply in wounds is conditioned to a very large extent by (a) the reaction of the exudate loss of alkaline reserve being conducive to bacterial proliferation and (b) the antitryptic capacity of the serum or lymph the presence of a low degree of antitryptic power tending also to encourage bacterial growth. Many bacteria lack the equipment of enzymes necessary to break down complex proteins into assimilable amino acids and peptides and the presence of active proteolytic enzymes in the bacterial environment presumably permits organisms of low

From the Department of Surgery, Columbia University and the Surgical Service, Presbyterian Hospital, New York.
Presented in the symposium on Antibiotic and Chemotherapeutic Agents before the Clinical Congress of The American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

chronic empyema of pleural decortication under the protection of penicillin demonstrates how a chemotherapeutic agent may aid the surgeon in attaining a physiological objective. In many long-standing leg ulcers the factor of superficial infection contributes to their chronicity, but success in eliminating the hemolytic streptococci, staphylococci or colon bacilli will not alone allow the ulcer to heal if the poor circulation in the fibrous ulcer bed cannot sustain the growth and continued vitality of an epithelial covering. Permanent healing may await restoration of normal blood flow in the affected extremity, removal of scar tissue, and application of grafts of healthy skin. There is now ample evidence that chemotherapy and other forms of local treatment of large decubitus ulcers are gestures of futility unless the nutritional debility of the afflicted patient is first corrected and when that has been done and all dead tissue removed plastic closure of the ulcers can be performed successfully in the face of a very considerable amount of bacterial contamination.

The large scale clinical investigation of the use of topical sulfonamide applications in prevention of infection in civilian accidental wounds, which was carried on under the OSRD during the war served to bring out very clearly the primary importance of the physiological condition of the wound and emphasized the limitations of chemotherapy in meeting this problem. Conclusions from this study (3) were recently summarized:

"1 Factors tending to delay or interfere with wound repair such as extensive tissue trauma, incomplete débridement, or improper or ill advised closure with tension, residual dead-space or implantation of foreign materials, will always predispose to the development of infection in accidental wounds.

"2 The use of chemotherapeutic agents in any combination and by any route does not prevent local infection of the wound when these predisposing factors exist.

3 Chemotherapeutic agents are probably of great value in preventing invasive sepsis and death from infection following accidental wounds."

Therefore the surgeon who attempts to lean heavily on the crutch of prophylactic

topical sulfonamides in the performance of reparative surgery will sometimes be disappointed, and many of his good results will have been obtained in spite of rather than because of the application of the drug. However, there appears to be a valuable place for the local use of penicillin, and perhaps streptomycin as well in the treatment of many established infections of wounds, in localized abscesses, acute empyema, suppurative arthritis and peritonitis, meningitis, mastoiditis, and bronchiectasis. This practice is in keeping with physiological management if the antibiotic is also given intramuscularly in full doses to control such invasive aspects of the infection as may be present, and if the topically applied drug is dissolved in a suitable vehicle. The vehicle which has given the best results in cases under my own observation has been normal saline, containing 1000 to 5000 units of penicillin per cubic centimeter administered either by intermittent aspiration and injection as in acute arthritis and empyema or in the case of infected wounds, by intermittent irrigation through a very small indwelling tube which is held in place by the dressing or by loose gauze packing. In order to achieve the maximum effect, the drug must be applied so as to maintain a high concentration continuously in all parts of the wound.

Therefore, to summarize this initial phase of our discussion, the primary concern of the surgeon in the care of the localized infectious lesion should be to conserve and augment the natural mechanisms of the body for combating infection. Surgical procedures can be of great value in removing tissues which have lost their capacity to react to infection in improving blood supply, and in providing physiological conditions favorable to healing. Penicillin, streptomycin and the sulfonamides will display their greatest value if used with proper discrimination in conjunction with surgery directed toward these ends.

The need for constant attention to the physiological mechanisms of infection is even greater in the management of severe invasive infections, such as peritonitis, septicemia, and gas gangrene where their derangement seriously threatens the life of the patient. As one studies these infections at the bedside and in

the experimental laboratory one is increasingly impressed with the similarity between the physiological condition of patients with severe infection and that of patients in shock due to blood loss, to crush syndrome to intestinal obstruction or to severe burns. Much of what has been learned about the prevention and treatment of shock during the last war may properly be applied to the treatment of patients with severe infections.

As used here the term shock connotes an acute maladjustment in the distribution of sufficient available oxygen in the blood to meet the needs of critical organs of the body particularly the liver adrenals, kidneys, and heart muscle. Shock as so defined may be initiated not only by reduction of blood volume below that required for maintenance of circulatory dynamics but also by loss of peripheral vascular tonus by failure of proper oxygenation of the blood and by a pathological alteration in the composition or physical condition of the blood.

Peritonitis perhaps illustrates the various aspects of shock in infection better than any other surgical infection because it brings into simultaneous interplay a number of factors which contribute to development of shock as it has been here defined. During the past 2 years I have had the opportunity of studying this subject extensively in dogs in the experimental laboratory in collaboration with Doctors John H. Kay and Donald G. C. Clark (3, 9, 10). During the critical period of the disease salt and water are lost externally in vomiting, or in decompression of the paralyzed bowel and internally into the edematous peritoneum and intestinal wall. Plasma protein is taken out of circulation in the process of formation of peritoneal exudate. Many red cells are destroyed by hemolysis and others are lost from effective use as oxygen conductors by stagnation in the engorged vessels of the peritoneum and by the formation of sticky conglutinated masses of what Knisely has aptly called sludge. All of these factors unless corrected, contribute to the development of a progressively falling blood volume. However replacement of the lost volume of blood does not necessarily relieve the shock state in peritonitis, a fact which was demon-

strated during the war by Emerson and Ebert. One reasonable explanation of this is that the lysis of Gram negative bacteria present in the exudates of peritonitis permits the liberation of endotoxins into the portal and systemic circulations, which specifically impair the functions of capillaries and of cell membranes not only in the liver to which these toxins are presumably carried in their most concentrated form but in other essential organs as well (15). Therefore, the shock state in peritonitis is probably compounded of reduced blood volume, plus the direct toxic action of products of bacterial and tissue origin. An interesting practical sidelight on the activity of endotoxins of Gram negative bacilli is the evidence now available from several sources (16) that the sulfonamides exercise a nonspecific protective action in animals against the lethal effects of such toxins. The beneficial use of sulfonamide prophylaxis and treatment of peritonitis may be attributable as much to this antitoxic action as to the repression of bacterial growth in the peritoneal cavity. We should therefore not be hasty to abandon entirely the use of sulfonamides in peritonitis in favor of the newer antibiotic agents, such as penicillin and streptomycin until opportunity has been afforded to study more fully the comparative usefulness of these agents in combating the factor of toxemia.

Still another physiological system which appears to be thrown out of balance in peritonitis is the equilibrium between the plasma proteolytic enzyme and its respective inhibitor. This is essentially the same system which Fleming was concerned with in his study of wound exudates, to which reference was made in the first portion of this paper. The proteolytic enzyme which is normally available for activation in plasma and which is most readily demonstrated through its lytic action on fibrinogen and fibrin, presumably exists for the most part in the form of an inactive precursor. However just as is the case with pancreatic trypsin which it resembles, the plasma protease may become converted to its active form through contact with activators of bacterial and tissue origin. The so called fibrinolysin of the hemolytic streptococcus is, in fact merely an activator of the

plasma proteolytic enzyme system and in conformity with conventional terminology, has been renamed 'streptokinase' (12). The action of the plasma protease is normally counterbalanced by a circulating inhibitor factor corresponding to and closely resembling the pancreatic trypsin inhibitor. However it was found (10) that in the crisis of peritonitis in the dog this equilibrium is thrown out of balance and the 'escape' of the lytic principle is evidenced by an increase in the lytic activity of plasma against both fibrinogen and fibrin. Lysis of circulating fibrinogen and perhaps of prothrombin as well appears to explain why the blood of animals and patients in shock from peritonitis and from other causes sometimes fails to clot. The work of Grob suggested a method of determining the significance of increased plasma proteolytic activity in the pathogenesis of peritonitis. He had shown that increasing the titer of protease inhibitor by repeated intramuscular injections or oral feeding of trypsin is accompanied by a marked increase in the ability of animals to withstand the local digestion of tissues caused by subcutaneous injection of proteolytic enzymes of animal and bacterial origin. My colleagues and I therefore undertook to evaluate the protective influence of repeated trypsin injections against the lethal sequences of appendiceal peritonitis, and obtained an interesting result. Peritonitis was produced in 18 pairs of dogs by appendiceal ligation; one of each pair had received daily intramuscular injections of crystalline trypsin for 12 days and the other was a control. The management of the animals was in all respects identical and the healthier looking dog of each pair was always selected to be the control. The end result was the survival of 15 trypsin prepared animals and of only 6 controls. The animals which had received trypsin preparation failed to display many of the morbid clinical and laboratory signs which were conspicuous in the controls. It may be added that efforts to influence the morbidity and mortality of the experimental disease in dogs were far less successful when chemotherapeutic agents were employed. The mortality rate in 15 dogs treated with large doses of penicillin was 33% per cent (10). These experimental studies are

mentioned here in order to indicate that there are important aspects in the morbid process of an established infection which are not likely to be countered solely by the administration of bacteriostatic chemotherapeutic drugs. We must continue to recognize that the infected patient is a more complicated system than a laboratory culture and that recovery from infections requires the stabilization or readjustment of many physiological disturbances which the infection has created.

Therefore in treating the toxemia of severe infection, all possible use should be made of penicillin, sulfonamides, and streptomycin but the fundamental physiological disorders that derive from bacterial infection must also be kept in mind, so that adequate supportive treatment, as well as chemotherapy may be given. The following aspects of supportive treatment deserve particular emphasis.

1. Patients with serious invasive infections including peritonitis, bacteremias of all types, gas gangrene, and meningitis should be handled with the same concern for maintenance of blood volume as is employed in modern treatment of severe burns, and of hemorrhagic or postoperative shock. This will require generous use of whole blood, of plasma, and of saline and glucose solutions, guided by frequent estimations of hematocrit, serum proteins and electrolytes and urinary output.

2. These patients should not be permitted to suffer from even temporary protein starvation. The patient with an acute infection is undergoing very active protein catabolism; the quantity of nitrogen excreted in the urine reflects a utilization of protein which is equivalent to three or four times the normal daily requirement. Still more is being continuously lost in the formation of inflammatory exudates. For example a patient with empyema may be losing the equivalent of a pint of plasma each day in the form of purulent thoracentesis fluid. Unless an equivalent amount of protein is supplied in the diet or by parenteral injections, a rapid depletion of liver and muscle protein is bound to occur thereby undermining the resistance of the patient and aggravating the problem of his convalescence. All patients with infections should be maintained on a high protein, high caloric intake and a

record should be kept of the amounts of food actually ingested. If oral feeding is contraindicated protein should be given parenterally by a suitable hydrolysate, with glucose. The average adult patient should receive at least 125 grams of protein and 2500 calories, daily.

3 The utilization and excretion of several of the vitamins is much increased during acute and chronic infections. After studying the requirements of patients in shock from various causes Levenson and his associates have recommended the following daily doses of vitamins during the period of acute stress

Ascorbic acid	10 gram
Thiamin	50 mgm.
Riboflavin	50 mgm.
Nicotinic acid	500 mgm.

After the period of critical illness has passed these doses may be reduced to approximately one fifth of the above figures.

In view of the possibility that some of the physiological derangements in severe infections are related to inadequate storage of these vitamins, this aspect of balanced supportive treatment should not be neglected.

4. Since the absorption of toxic breakdown products of bacteria and tissue is still the basis of toxemia in infection much caution should be exercised before abandoning to chemotherapy exclusively the treatment of conditions in which surgical intervention has been our principal life-saving weapon in the past. The evidence may now justify the nonoperative treatment (1) of acute hematogenous osteomyelitis and other invasive infections where the susceptibility of the causative bacteria to penicillin may in most cases be assumed, but it is doubtful that chemotherapy will ever be more than a valued adjunct to surgery in the treatment of conditions such as appendicitis and its complications, and chronic pulmonary suppuration and gas gangrene. Penicillin in large doses may be of definite value in established peritonitis following neglected appendicitis, as the recent report of Crile has shown but it will not compete with surgery as the principal treatment of choice in acute appendicitis.

SUMMARY AND CONCLUSIONS

1 Chemotherapeutic agents should be selected, and used, with a view toward aiding in the natural resistance of the body to infection.

2 Although it is important, wherever possible, to employ treatment directed specifically against the bacteria involved in an infection, the treatment of associated disorders should not be neglected. In certain conditions the persistence of the infection is entirely dependent on an underlying physiological lesion, and in these cases, chemotherapy is of only secondary importance.

3 Rational treatment of severe infection characterized by toxemia demands supportive measures as well as administration of chemotherapeutic agents. Particular attention must be given to maintenance of blood volume, provision of an adequate intake of protein, calories and vitamins, and surgical removal of the cause of the toxemia.

4. Study of the pathologic physiology of the toxemia of infections should be encouraged, in the hope that mortality from these conditions may be still further reduced.

SYMPATHETIC INTERRUPTION IN CASES OF TRAUMA AND IN POSTTRAUMATIC STATES

HARRIS B SHUMACKER Jr., M.D., New Haven Connecticut

THERE can be no doubt that an erroneous impression has persisted from the past concerning the favorable influence of war upon medical progress. Actually the period of war must be recognized as having resulted in retardation of progress as compared with what might have come from a period of peace whether measured by the health and longevity of the world population the adequacy of undergraduate and graduate training of physicians or the advancement of fundamental and applied knowledge. It behooves us then to salvage from the war effort all accomplishments which may be useful in the conduct of any future military engagement and more particularly those contributions which may aid in peacetime practice.

In the recent conflict not only was military medicine on a higher plane than in any preceding war but circumstances permitted a better evaluation of the preventive diagnostic and therapeutic means which were utilized. Of especial importance in this regard was the creation by the Surgeon General of special centers for the care of certain types of injuries and disease, a plan which made possible careful study of these disorders and of their treatment under favorable circumstances by a group of medical officers competent for this task by special interest and professional preparation. Their study was however necessarily limited more or less to the later manifestations of these conditions, although prompt evacuation sometimes placed in their hands patients ill or disabled for only a few weeks. In addition, in spite of the difficulties resulting from the necessity for prompt evacuation of patients certain deficiencies in facilities and other cir-

cumstances arising from military demands a considerable number of very informative reports have come from the Forward Areas. Such contributions naturally are attributable primarily to the proficiency and scientific interest of those who conducted them. Great credit must be given however, to the Surgeon General's Office and to the consultant system utilized in the various theaters of command and to their earnest, if not always successful efforts to assign duties to medical officers according to their training and ability, to support them whenever possible with adequate equipment and to stimulate the careful recording of case records.

The segregation of patients with vascular disorders and abnormalities involving sympathetic function in the Vascular and Neurosurgical Centers permitted a study of many of the problems for which sympathetic interruption has been recommended as beneficial in numbers rarely if ever before approached. This information has been supplemented by observations of these and allied conditions in Forward Areas. It is the purpose of this communication to inquire into the rôle of temporary and permanent interruption of the sympathetic nerves in the care of patients who have sustained trauma. No detailed analysis will be attempted but rather a general presentation of the problem as it developed in my own experience and as it has been presented by other medical officers in the current American literature. For the sake of brevity I shall omit reference to the valuable work of numerous investigators whose contributions before the war established the principles and fundamental background for the application of sympathetic interruption in the surgery of warfare. One cannot emphasize too strongly the value of these investigations. Certain personal observations from the recent war have already been recorded in more detail elsewhere by my associates and me (26-29) and other reports

From the Vascular Center, the Mayo General Hospital, Galesburg, Illinois, and the Department of Surgery of the Yale University School of Medicine, New Haven, Connecticut.
Presented in the symposium on Fractures and other Traumas before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

covering sympathetic interruption in such conditions as the post traumatic vasomotor disorders, cases of injury to major arteries, caualgia, and frostbite will be reported subsequently. The problems under consideration will be discussed primarily from the standpoint of the efficacy and the limitations of these procedures in therapy whereas consideration of the often poorly understood underlying physiopathological mechanisms by which the sympathetic nervous system is involved as a component in these various states will be omitted.

In an effort to clarify the matter the various traumatic conditions will be presented under several headings although it is realized that in any given patient the condition may not be a pure one fitting precisely into any one of these categories but may have features common to several of them.

ARTERIAL STUPOR OR SEGMENTAL ARTERIAL SPASM

It has long been recognized that trauma which actually inflicts no direct injury to an artery may initiate a reflex spasm of such degree that blood flow through this vessel may be interrupted with resultant gangrene or ischemic paralysis in certain instances. Specific directives were issued giving proper instructions for the management of this condition. No large group of such cases is available for study. Presumably they were handled in the following manner by periarterial sympathectomy when the artery was exposed in the course of débridement, and in all instances by prompt and repeated use of sympathetic blocks and other efforts to release vasoconstriction until permanent restoration of normal blood flow had been achieved. It is likely that a significant number of cases of segmental arterial spasm involving major arterial stems must have occurred among the thousands of cases of trauma to extremities. The best index of the efficacy of treatment is the fact that only a few instances of ischemic difficulties arising from this condition were seen in the Vascular Centers into which were funneled most of the patients with vascular injuries. These exceptional cases—tragic examples of loss of limb and of function without

direct arterial injury—likewise serve as a stern warning for the necessity of prompt and proper treatment.

From the war experience it would appear that the following points are important in the management of this condition. Physicians must be aware of its existence and trained in its recognition. It must be considered a possibility in any case of injury in which the peripheral pulses in the limb have disappeared with resultant evidence of ischemia, and particularly when there is no significant external bleeding or hematoma and no sign of an arteriovenous shunt. It is important that operators be trained to recognize the spastic artery and differentiate it from other conditions following trauma, such as compression by hematoma or intra-arterial thrombosis. In general, the artery will be found to be pale and narrowed in caliber with good pulsation above the area of constriction and with weak or absent pulsation below. Generally there will be no hemorrhage in the artery wall. There will be no firm intra-arterial mass or distention of the lumen, conditions which are commonly observed in embolism or thrombosis.

Once the condition has been diagnosed or is suspected every effort should be made to release vasoconstriction. If the artery is exposed at operation its outer wall should be infiltrated with procaine and it should be carefully stripped of its adventitia. Warming of the body but not of the involved limb should be carried out. A sympathetic block or a spinal anesthesia should be done promptly. If vasodilatation and return of pulsations follow the block or spinal anesthesia but last for only a short while sympathetic blocks should be repeated at frequent intervals. Should the benefit following each block be of short duration, one should not hesitate to proceed with operative sympathectomy or with alcohol block if the patient's condition makes operation ill-advised. The limb itself should be protected from trauma and infection and should be left exposed to room temperature. Local warmth should never be applied unless there is conclusive evidence that one is dealing purely with a remedial condition of arterial spasm without any organic interruption of the continuity

of blood flow. If sustained return of normal blood flow is difficult to achieve promptly and there is no associated injury or disease contraindicating such treatment, anticoagulant therapy should be instituted without delay in order to inhibit thrombosis in the affected artery and in its collaterals.

No data are available as to the incidence of failures in patients who have been treated promptly and adequately. It may be anticipated that success will accompany such a program of treatment.

TRAUMATIC INJURY OF MAJOR ARTERIES

Though they did not constitute a considerable proportion of battle casualties, cases of direct trauma to major arteries presented a difficult therapeutic problem. Odom reported that there were 837 vascular injuries to major arteries among the 92 030 battle casualties sustained by the Third Army during a 9 month campaign in Europe, an incidence of 0.9 per cent. Four hundred and twenty three of the 1833 amputations performed were necessitated by injuries to blood vessels (23 per cent). De Bakey and Simone stated that 0.96 per cent of 163 980 battle casualties were wounds of arteries and 618 of the 3177 amputations from the Mediterranean and European Theatres were carried out because of arterial injury (19.5 per cent). In a smaller series of cases, Kirtley found that 20 per cent of major amputations were done because of inadequate blood supply. Bradford and Moore reported that 0.7 per cent of 16 000 surgical admissions to their hospital had injuries of important arteries. It may be concluded that slightly less than 1 of each 100 soldiers wounded in combat sustained an arterial injury and that approximately 20 per cent of all major amputations were performed because of trauma to blood vessels.

Medical officers were instructed by directive to utilize sympathetic blocks in all injuries of major arteries in which the circulation was definitely or questionably jeopardized. The results of this procedure for obvious reasons, are difficult to analyze. The additional therapy in cases of arterial injury was never dependably identical. In some the concomitant vein was ligated while in others it was left intact.

Although ligation and division of the artery were recommended in certain cases ligation in continuity was performed. In some, an effort to maintain the continuity of the blood flow by suture or nonsuture methods was attempted while in the majority no such efforts were made. In most instances adequate control of any attendant shock was promptly accomplished but not in all. There was not uniformity in the application of measures to prevent infection and additional trauma nor in regard to the temperature to which the limb was exposed. Indeed, adequate sympathetic anesthesia was undoubtedly not always obtained by efforts to block the chain. Of equal import is the fact that sympathetic blocks were carried out as often as necessary in some cases and too few blocks spaced over too wide intervals in others. Of perhaps even greater importance in making evaluation of this procedure difficult is the varying character of the injury incurred.

In order to arrive at valid statistical conclusions one would not only have to segregate treated and untreated cases according to the location of the arterial injury but would have to be certain that the two groups were comparable from the standpoint of the character of the local lesion, the associated trauma and the general state of circulation. Actually the extent of local trauma varied. In certain patients the artery was thrombosed without laceration in others simply lacerated or severed in still others badly damaged over a considerable extent. Sometimes there was extensive local trauma with injury to collateral vessels, extravasation and edema, as well as associated fractures of varying severity or injuries to peripheral nerves. In contrast some patients had no associated lesion of any significant extent. Furthermore in spite of efforts to the contrary case records of patients were often deficient with regard to important factors concerning the character and the extent of the local and general injury and in regard to the therapeutic means employed. It must be remembered too that analysis of the results of sympathetic interruption solely on a basis of the incidence of gangrene necessitating major amputation as is sometimes done omits consideration of possible effects of this treatment upon subsequent

the exercise tolerance was not strikingly altered

The results of sympathetic interruption in cases in which blood flow through a major artery was interrupted by trauma indicated this procedure to be of definite benefit, in my opinion at the same time they clearly demonstrated that this procedure offered no guarantee against ischemic difficulties. With regard to civilian practice I believe the military experience would suggest that every lacerated artery be repaired if this were possible that sympathetic blocks be used promptly and as often as necessary, that when improvement with blocks is only transient permanent sympathectomy be performed by operation if feasible otherwise by alcohol injection. If sympathectomy is not carried out all additional aids in vasodilatation should be utilized such as reflex vasodilatation and the oral administration of alcohol. The limb is to be left exposed to room temperature and to be protected from injury and infection.

It is my impression that early sympathectomy will often prove helpful when procaine blocks are of little permanent help due to their transient benefit. In selected cases seen later after injury sympathetic blocks and more often sympathectomy will be found to be of considerable aid.

ARTERIAL ANEURYSMS AND ARTERIOVENOUS FISTULAS

Before the war sympathectomy or alcoholic infiltration of the sympathetic nerves had been used sufficiently often in cases of aneurysm and arteriovenous fistula to establish its usefulness as an adjuvant in their operative treatment. A number of surgeons during the war had occasion to employ sympathetic blocks or sympathectomy in such cases and held the opinion that they were useful aids. In the three Vascular Centers sympathectomy and sympathetic blocks were utilized in varying degrees. In general, these procedures were not employed at the Ashford General Hospital, and the brilliant results obtained there by Elkin and his associates furnish striking proof that large numbers of patients can be treated successfully without resorting to sympathetic interruption, though those of us who

have studied patients after sympathectomy have been convinced of its usefulness. At the De Witt General Hospital sympathetic interruption was used fairly extensively and was thought to be very helpful in selected cases (11). At the Mayo General Hospital a great many sympathectomies were performed. This experience has permitted me to evaluate the procedure carefully and to formulate certain concepts concerning its benefits and its limitations.

Sympathectomy tends to render the collateral circulation more efficient by elimination of vasoconstriction in the collateral vessels. Though sympathectomy may also contribute to improvement in circulation by fostering growth of new collaterals and though certain observations suggest that this may be true, convincing proof has not been demonstrated. When the collateral circulation appears insufficient according to carefully performed tests when a sufficient time has elapsed to have ordinarily brought about adequate collateral circulation and when such means as intermittent occlusion of the artery appear to be achieving little or no improvement, sympathectomy is indicated. It is also indicated in all cases with poor collateral circulation in which intense pain, infection, or threat of rupture make the necessity for early operation a real possibility. In the majority of cases the collateral circulation will be found to be adequate immediately or shortly after sympathectomy. In a number however the tests for collateral circulation may show improvement but may not become adequate over a period of months. Because sympathectomy has been accomplished one can in no sense assume that the collateral circulation will be invariably satisfactory or that gangrene or ischemic paralysis will always be prevented.

Sympathectomy is indicated in any case in which an aneurysm or fistula is associated with a peripheral nerve lesion and in which the collateral circulation is precarious indeed in any case with severe peripheral nerve injury and obviously impaired circulation regardless of whether tests for collateral circulation are satisfactory or not. It appears wise to do everything in these cases to make possible

early surgical treatment of the aneurysm or fistula in order to avoid delay in operating upon the damaged nerves. Occasionally one will find it advisable to perform sympathectomy as a safeguard in cases of vascular lesions of important main stem arteries when the location of the lesion makes accurate compression of the artery and testing of the collateral circulation impossible. It appears rational to perform sympathectomy in those cases with ischemic lesions distal to an aneurysm or fistula. It is indicated when there is significant vasospasm in the affected extremity. The procedure may occasionally be advisable when one or more of the important arteries in a limb have already been ligated or thrombosed and in which cure of aneurysm may entail ligation of other important arteries or collaterals. Sympathectomy may sometimes be required because of associated causalgia.

Sympathectomy need not necessarily be performed before operation the two procedures can often be carried out in one session. In every instance however one should retest the collateral circulation after sympathectomy and make certain that it is satisfactory before proceeding with the surgical treatment of the aneurysm or fistula.

After operation, sympathectomy will also be found to be an adjuvant in correcting certain difficulties which sometimes follow extirpation of an aneurysm or fistula. It is clearly indicated when there is annoying or incapacitating sensitivity of the hand or foot to cold in a patient whose place of residence and work or avocation make such exposure necessary and when improvement in symptoms is noted on exposure to cold during a period of procaine sympathetic anesthesia. It is useful in cases of persistent edema which have not improved upon conservative treatment. It is generally helpful and often dramatically so in cases of ischemic paralysis. It appears to foster return of nerve function in cases of peripheral nerve injury in which the circulation is impaired. It is also useful in the treatment of associated causalgia which is improved temporarily but not cured by sympathetic blocks. When a limb is found to be cold and pale or cyanotic after operation or

when gangrene is definitely threatened, sympathectomy should be utilized in some cases. It brings about gratifying restoration of good circulation though it will not always prevent gangrene. In regard to the two commonest circulatory disorders which may follow sympathectomy sensitivity of the limb to cold and decrease in exercise tolerance, the procedure has a very beneficial effect upon the former but rarely has a striking effect upon the latter.

It is my feeling that when sympathetic interruption appears to be indicated, permanent sympathectomy is generally preferable to procaine blocks, though blocks undoubtedly have a place in the treatment of certain cases. Sympathetic interruption seems justified for the indications which have been enumerated where no clear indication exists there seems to be no point in performing the procedure. It must be looked upon as a valuable adjuvant in the surgical treatment of aneurysms and fistulas. It cannot be relied upon as a certain guarantee against ischemic difficulties, nor can it be relied upon as a sure corrective for all functional disorders which may be present.

To have performed a sympathectomy does not relieve the surgeon of responsibility for utilizing carefully performed tests for collateral circulation for exercising every care to prevent destruction of collateral vessels at the time of operation and for preserving the continuity of the artery if possible.

THE POSTTRAUMATIC DISORDERS

The posttraumatic vasomotor disorders comprise a number of conditions about which many divergent opinions are held. Some would include only those cases with edema, pain, weakness, disability, atrophy, osteoporosis, and either vasoconstriction or vasodilatation. Others would include in this category various vasomotor disturbances following trauma, infection and such vascular disorders as thrombophlebitis. The discussion here will be limited to the difficulties following trauma or to trauma and associated infection. It has been my experience that these disorders may be characterized by various complaints and physical findings. In some

pain is present either at rest or more commonly with activity and weight bearing in others pain is absent. In some edema is massive, in others moderate or mild, and some have no edema at all. Some have evidence of vasodilatation the majority of vasoconstriction. Cyanosis, coldness, sensitivity of the part to cold and hyperhidrosis may be present in varying degree. Some have marked weakness of muscles, some virtual paralysis. Sensory changes may be present.

In a group of disorders so varied in their manifestations there is little wonder that treatment cannot be stereotyped and that results of therapy are not uniform. Those who have utilized sympathetic blocks and sympathectomy have been favorably impressed with the results of such treatment (32) as have my associates and I. It is not my feeling that such treatment should invariably be applied or that it can ever be utilized as the sole means of therapy. It is difficult to outline concisely one's views of treatment for such a complex problem but to do so as succinctly as possible the following suggestions are made.

In any case of trauma which is unassociated with injuries contraindicating such treatment, early active use of the part should be instituted. Obviously wounds must be debrided, fractures properly reduced and immobilized and every precaution taken to prevent infection. Whenever edema is present proper elastic support, elevation and gradual increasing use of the limb in dependency should be utilized. One must be sure to encourage the patient and to do everything to prevent development of an attitude of invalidism. If a real neuropsychiatric factor exists, it must be recognized and suitable treatment instituted.

Whenever there are signs or symptoms suggesting a reflex disturbance such as is under consideration and these manifestations prevent active use of the limb or do not improve rapidly with such activity and with proper associated treatment, sympathetic blocks should be tried without delay and should be repeated as frequently and as often as necessary. If they bring about transient improvement but appear to have no permanent

benefit, one should not hesitate to proceed with sympathectomy. In certain cases it will be preferable to employ local procaine infiltration first before performing sympathetic blocks. If such local infiltration brings about temporary benefit but no cumulative improvement and an irritable trigger zone seems to exist which can feasibly be excised, such a procedure may be indicated. In connection with local infiltration it is proper to introduce here the technique of procainization in the early treatment of sprains and strains which was found very effective in army personnel (20). That at least part of this benefit results from blocking the sympathetic impulses is suggested by the fact that such injuries have been treated with equal success by sympathetic blocks (32).

In the treatment of the late sequelae we have found that many patients obtain an excellent result from active use of the limb, physiotherapy and elastic support when needed. It was found that in a small number of patients manifestations very similar to those generally observed were either initiated or perpetuated by neuropsychiatric factors. In such cases psychiatric therapy is obviously required. In some a brilliant result is quickly achieved, others are very refractory. In rare cases responding unsatisfactorily to psychiatric treatment, sympathetic interruption may be a useful adjuvant in correcting certain manifestations such as persistent massive edema. When the simpler means of treatment show no promise sympathetic blocks should be carried out. Occasionally a patient is helped decidedly by blocks but ordinarily any beneficial effect is transitory. In general sympathectomy is the procedure of choice for such cases. Except for cases in which a fundamental psychiatric problem has been unrecognized before operation, the results are gratifying. The manifestations of vasospasm and sympathetic overactivity respond dramatically: cyanosis, coldness, hyperhidrosis are relieved and sensitivity to cold is cured or improved. Edema is generally lessened sometimes dramatically. Pain is generally improved and is sometimes completely eliminated. Sympathetic interruption can never be regarded however as the sole

form of treatment. Whether it is used or not, the patient must be encouraged active exercise must be enforced and edema must be dealt with by elastic support, rest, and gradually increasing dependency.

No data have been made available in regard to possible usefulness of sympathetic interruption in the healing of fractures. It has been demonstrated however that sympathectomy may be extremely useful in reducing edema and in eliminating marked vasospasm before bone grafting and other plastic restorative procedures.

CAUSALGIA

The war afforded an unparalleled opportunity for studying large numbers of cases of causalgia and their treatment (2 12 18 24, 31 33). In general excellent results from sympathectomy were obtained. The majority of patients obtained complete relief and improvement was almost invariably noted in the remainder. It has been the common observation that the results were better in the upper extremity than in the lower. Certain observations suggest that the poorer results in the lower extremity may be due in part to incompleteness of the ganglionectomy—that it may be necessary to sympathectomize completely the area of the nerve lesion as well as that to which the pain is referred (2 33). The series of Rasmussen and Friedman suggests that postganglionic operations for the upper extremity are inferior to the commonly employed preganglionic operation in the treatment of causalgia. Although such observations have not been uniformly made it has been my experience that the more severe the pain the more apt one is to obtain complete relief following sympathectomy. Since the pain is generally more severe in the upper extremities this may be an additional factor in the somewhat higher incidence of complete cures in these cases as contrasted with those having involvement of the lower extremities. In general it is thought that the results are more favorable the earlier treatment is instituted.

Some surgeons have utilized sympathetic blocks only as diagnostic and prognostic tests and some (33) have never obtained permanent

relief from any number of procaine sympathetic blocks. Though we found that sympathectomy was necessary in the majority of cases, my associates and I observed permanent relief from sympathetic blocks in numerous instances. It is our feeling that one should proceed with sympathectomy if relief of pain is limited to the period of sympathetic block and that a series of blocks should be tried in patients who experience prolonged relief after a procaine block. If the relief does not become progressively more prolonged as additional blocks are carried out, they should be abandoned and operation should be carried out. It is apparent from the experience in the war that a rare patient with causalgia may be cured by neurolysis or neurothraphy or by artificial fever therapy. A rare case, too, may be associated with definite neuropsychiatric features and respond favorably to psychiatric therapy (16). In general, however, sympathectomy is required. Altogether the results are brilliant.

PHANTOM LIMB PAIN AND AMPUTATION STUMP PAIN

Few wartime observations have come to my attention concerning the use of sympathetic interruption in the distressing phantom limb syndrome and in amputation stump pain. To be sure, a few cases of pain and vasospasm in minor amputation stumps with improvement or relief following sympathectomy have been recorded (12) and I have made similar observations. In addition, Pool has used sympathectomy in conjunction with cordotomy in a few cases of phantom limb pain and has the impression that sympathectomy may be helpful in relieving the burning pain seen in this syndrome. In general, however, no studies have been made of sympathetic interruption in the complex amputation stump pain following major amputations nor in the phantom limb syndrome—in all likelihood a reflection of the infrequency with which these difficulties have occurred in military personnel. I believe the primary lesson to be learned from the experience in the recent war deals not with the treatment of amputation stump pain and phantom limb pain but with their prevention by proper operative technique, by early active

use of the stump and by careful conditioning of amputees to the normal physiological sensations of a phantom limb which they almost invariably experience (19). I have had occasion to observe in patients in whom such procedures were performed for other reasons that the normal phantom limb sensations may be temporarily but not permanently relieved both by sympathetic blocks and by sympathectomy. My own small experience would lead me to believe that sympathectomy rarely has a place in the treatment of amputation stump and phantom limb pain.

THE INJURIES DUE TO COLD

Opinions are at wide variance in regard to the rôle of sympathetic interruption in the injuries due to cold—frostbite, trench foot, and immersion foot or hand. Elsewhere (28) I have attempted to review this subject. It appears clear that although other factors may have a part, thrombosis of arteries and arterioles is the primary factor concerned in the production of gangrene—the most disastrous sequel to injuries from cold. It is further well established that vasoconstriction is the primary response of the body to exposure to cold, and that, although a transient period of reactive hyperemia may follow vasoconstriction is one of the commonest sequela. These facts would suggest that efforts to block sympathetic impulses and combat vasospasm might be fruitful in the treatment of the acute and later manifestations of these disorders.

Numerous students have advised against sympathetic interruption in the early stages of trench foot, immersion foot, and frostbite, perhaps on insecure grounds. There is little information from our own war experiences concerning the effect of these procedures in the early treatment of frostbite although some of our allies and opponents reported good results with sympathetic blocks and periaxillary sympathectomy. Davis and associates, who felt that it was important to release vasoconstriction as rapidly as possible, found that direct blocking of the sympathetic pathways was the only means of accomplishing this end in severe high altitude frostbite. Southworth has treated a few cases of early frostbite by sympathetic blocks with apparent

benefit. Berson and Angelucci noted no improvement with sympathetic blocks in a few early cases of trench foot with massive edema, but obtained temporary diminution of pain and tenderness in milder cases. Leigb reported that sympathetic blocks were of no aid in the early treatment of trench foot. Edwards and his co-workers in a small group of cases, found that sympathectomy gave good results in the early treatment of trench foot with gangrene but that it was not helpful in cases with tender painful and aching feet. No studies have come to my attention concerning the use of sympathetic interruption in the treatment of the acute phases of the immersion injuries.

With regard to treatment of late manifestations of these disorders, the rôle of sympathetic interruption has been more clearly defined. The results of sympathectomy are good in properly selected cases of frostbite. The procedure is useful in cases of gangrene, excessive hyperhidrosis, persistent marked vasospasm, sensitivity of the hand or foot to cold and sensory changes. Southworth reported some observations suggesting that repeated procaine blocks, alcohol blocks, or sympathectomy may be helpful. Berson and Angelucci reported that sympathetic blocks were useful in late cases of trench foot with vasospasm, and that the improvement in treated limbs was faster than in the non-treated contralateral extremities. Although my associates and I were not impressed with the usefulness of sympathetic blocks in the late treatment of trench foot, we obtained conclusive evidence of the benefit of sympathectomy in selected cases. Sympathectomy unfortunately rarely is of aid in alleviating the pain which is so commonly experienced on weight bearing. It is particularly helpful in cases of gangrene, in marked hyperhidrosis, especially if associated with maceration of the skin and secondary infection in reducing the severity of symptoms in patients with sensitivity of the extremity to cold and in certain cases in which there is disturbance of sensation. Patterson found that sympathetic blocks improved temporarily the peripheral pulses, decreased numbness and pain, and abolished hyperhidrosis in the Attu casualties,

but observed that the beneficial effect was limited to the duration of sympathetic anesthesia. Southworth felt that sympathectomy produced beneficial effect upon the late manifestations of immersion foot although it had little effect upon deep pain.

Because such contradictory opinions are held by different observers it is exceedingly difficult to summarize any lessons which may have been learned in the recent war concerning sympathetic interruption in the treatment of the early stages of the injuries due to cold. I think it is fair to say that at least no harm has resulted from the use of such procedures and that their use for further evaluation is warranted. There is much to suggest that they may be very helpful especially if applied early and particularly in cases in which gangrene is threatened or existent. It is my feeling that if transient improvement without permanent benefit is noted following blocks, especially in cases with marked ischemia, one should seriously consider early sympathectomy. With regard to the later stages of these injuries, it is clear that sympathectomy has a definite though limited place in therapy. Though repeated sympathetic blocks may occasionally result in benefit, sympathectomy is generally required. Sympathetic interruption cannot be looked upon in any case as the sole means of therapy. One must, under all circumstances, protect the injured limb from trauma, infection and from external heat in the acute phase. There is much to suggest that anticoagulants should be employed in early cases. Conservatism should be practiced with regard to gangrene and necessary amputations. Physiotherapy and active exercise should be utilized after the acute phase is passed. Shoe corrections, psychotherapy and other means should be used when indicated. It is my opinion that further experiences will confirm the usefulness of sympathetic interruption in alleviating certain complaints late in the course of these disorders and that they may well prove of value in the early stages.

SUMMARY AND CONCLUSIONS

The experiences during the recent war have in general confirmed pre-existing impressions concerning the usefulness of sympathetic

interruption in cases of trauma and in the posttraumatic states. Certain new applications of these procedures have been established. The war experiences have been particularly valuable in providing large numbers of cases for study with consequent better evaluation of the specific indications, the merits and the limitations of sympathetic interruption. It would seem that permanent sympathetic interruption may yield gratifying results in some instances in which precise blocks give unsatisfactory results. With regard to certain types of injury there are differences of opinion concerning the usefulness of these procedures. In the presentation of this problem an effort has been made to take into consideration the studies of various investigators, though the views expressed concerning controversial issues have necessarily been influenced by personal experiences.

THE TRANSPORTATION OF SOLDIERS WITH FRACTURES

WILLIAM J STEWART M.D., F.A.C.S., Columbia, Missouri

THE transportation of a soldier with one or more fractures usually compounded was one of the major medical problems encountered in the European Theater of Operations. In general most of the patients, immediately after wounding were transported by ambulance from the aid stations to the forward hospitals and then by train, boat or airplane to the rear echelon hospitals.

The past standard practices of transporting patients with fractures recommended by the Army Medical Corps were reviewed by the consultants and somewhat modified before the advent of major hostilities on the continent. The major modification was made in regard to the transportation of fractures of the upper extremities.

Almost everyone consulted agreed that the Murray Jones arm splint was an awkward device to apply and it was felt by most doctors that this awkwardness, combined with certain dangers of excessive pressure in the axilla, offset any good factors about the splint. Accordingly the medical officers were not encouraged to use it. Most upper extremity injuries were very simply and easily handled by simply binding the affected arm to the trunk with a sufficient number of triangular bandages. This provided good comfortable immobilization and obviated the necessity of applying a cumbersome piece of apparatus. In addition transportation by litter in an ambulance was a much simpler procedure than it would have been if this splint had been used widely.

Upon arrival at a field or evacuation hospital, or any hospital where surgery on the injured upper extremity was performed a plaster velpau or modified plaster shoulder spica dressing was applied after surgery and was termed a transportation plaster splint for the next stage in the evacuation of the patient.

This splint was either removed and the wound was inspected and the splint then was reapplied or else it was left intact by successive medical officers in the line of evacuation, according to their best judgment. Eventually the patient reached a general hospital where he was to be hospitalized for the next stage in his treatment. At this hospital the "transportation plaster" was removed and appropriate therapy usually skeletal traction was instituted to care for the fracture.

The first splint applied for the transportation of fractures of the long bones of the lower extremity was almost universally the army half ring splint. This was applied at the forward dressing station and remained in place until the patient was received at the field or evacuation hospital for his initial definitive therapy. The ambulance drivers and others responsible for his care during transportation from the aid station to the forward hospital were instructed to release the traction provided by the army hitch which was, in most instances, applied over the patient's shoe of the affected extremity. In the event the foot had been injured together with the long bones of the lower extremity the extremity was simply held in place in the half ring splint by means of triangular bandages, usually five in number and no attempt was made to apply traction. I observed a few individuals arriving at evacuation hospitals who had had undue pressure caused by the army hitch, or who had had the hitch in place many hours without release, but I cannot recall a single instance where any permanent damage was done by this procedure. I was favorably impressed by the comfort with which most soldiers with extensive fractures were transported from forward aid stations to evacuation hospitals in the army half ring splint.

After initial definitive treatment—debridement, etc.—at the field or evacuation hospital these patients, for the most part were encased in one and one-half plaster hip spicas for

Presented in the symposium on Fractures before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-30, 1946.

1. single extremity, or double spicas when both legs were involved and removed to the next hospital in the line of evacuation. These spicas were very well padded affairs. Plaster and padding were split and cut down to the skin up to the hip joint on the affected side. The legs of the plaster were joined with one or more plaster ropes or wooden struts to provide for stability. The patients who were received at ear echelon hospitals in all of these transportation plasters both for the upper and lower extremities, were for the most part remarkably comfortable. Shock was minimized. Pains were not an outstanding complaint, and dressings over the operative areas were retained in place, requiring minimal attention and inspection.

Before the advent of major hostilities in Europe the American Army Medical Corps was given the experience of the British in regard to transportation plasters. The British recommended the use of a hanging plaster for fractures above the elbow joint and the use of Tobruk splints for lower extremity injuries.

The hanging plaster was found by most American medical officers to be unsuitable because it did not immobilize the fracture during a long rough ride on a litter in an ambulance. Most patients complained of pain. The Tobruk splint was not regarded favorably by American medical officers because of the lack of immobilization of a fracture of a femur unless it happened to be just at, or immediately above, the knee joint, and because of the consequent pain the patient experienced.

I myself tried on many occasions to demonstrate a Tobruk splint to American medical officers and had a most difficult time applying it, much more trouble in fact than was experienced in applying the large one and one half or double plaster transportation hip spica.

There were many modifications of the Tobruk splint but, in general it consisted of 1. Adhesive traction straps applied to the skin along the full length of the extremity with padding over the malleoli.

2. An overlying snugly applied long leg plaster splint encasing the foot to provide support and minimize rotation of the extremity.

3. Slots in this plaster in the region of the malleoli through which the traction straps were passed.

4. An army half ring splint supporting the whole extremity in plaster with the traction straps tied over its end.

5. The incorporation of a windlass arrangement in these straps theoretically to provide skin traction to the injured extremity.

Undoubtedly, the British transportation plasters, namely the hanging plaster and Tobruk splint, used less material than did the American army's spicas and velpaus, and also could be applied with the aid of less personnel but the patients were definitely not as comfortable as in the American devices. The British medical units had less material and fewer personnel than did the American counterparts and it is my own feeling that these transportation plasters were developed to meet the material and personnel shortages of the British Army.

The Tobruk splint was used upon occasions by American medical officers and an attempt was made by one of the army consultants Lieutenant Colonel John Manning to follow up all of these cases in the Ninth Army. The number of cases that he was able to contact was nowhere near as impressive as the British figures but the conclusions reached by Lieutenant Colonel Manning substantiated the general belief that (1) There was no uniformity in the types of splints used (2) the transportation of such patients was accomplished with much more pain and discomfort than those encased in plaster spicas (3) the problem of retaining dressings in place in the upper thigh was much more difficult than when a spica was used.

Translating these lessons to civilian life it seems to me perfectly logical to recommend the abandonment of the use of the Murray Jones arm splint as a first aid appliance. I believe civilian patients can have upper extremities particularly when the humerus is involved bound rather snugly to the trunk by gauze or elastic bandages and can be transported in comfort. I should certainly recommend the use of a plaster velpau type of dressing if a compounding wound has been suffered which has been débrided or closed in

a patient who must be transferred to some other hospital for long term care. When civilian injuries involving the long bones of the lower extremities are encountered the army half ring splint with foot piece and army hitch reasonably well padded over the dorsum of the foot provides an excellent device for transportation. In the event a compounding wound has been encountered which has been debrided or closed a well padded plaster spica applied to the extremity without regard to the problem of reduction of the fracture serves as an excellent transportation device.

CONCLUSIONS

1. The Murray Jones arm splint was felt to be cumbersome and difficult to apply. Much more comfortable and efficient immobilization

was obtained by binding the injured upper extremity to the patient's trunk.

2. The plaster velpeau and modified shoulder spicas were preferred to hanging plaster in transporting patients after initial surgery.

3. The army half ring splint with army hitch is an excellent device for transporting fractures of the lower extremity.

4. One and one-half or double hip spica plasters are recommended after initial surgery and are much to be preferred to the British transportation devices labelled Tobruk splints.

5. The above devices, consisting of patient body immobilization plaster velpeaus & shoulder spicas, army half ring splints with foot rest and army clove hitch, and plaster transportation spicas can well be recommended for civilian use.

PENICILLIN IN EXPERIMENTAL INTESTINAL OBSTRUCTION

A Summary of Observations with Reference to Their Clinical Application

ALEXANDER BLAIN III M D Ann Arbor Michigan

THE mechanism of death in intestinal obstruction is only poorly understood. Previously death in all types of obstruction was ascribed to a tox-

It is now known that the vomiting associated with high obstructions produces profound chemical changes in the body and that these may be alleviated by the parenteral administration of salt and water. The studies of Wangenstein and others have shown that the relief of intestinal distention does much to reduce associated shock and the hazards of operative intervention. In spite of the advances of recent years in the management of bowel obstructions we still find 1 patient out of every 5 or 6 dying after operation for acute mechanical obstruction of the small bowel (5).

It is thus obvious that more must be learned concerning the pathology of intestinal obstructions in order that new surgical adjuncts can be developed to diminish the hazards associated with such lesions.

When penicillin became available for experimental purposes, we were given the opportunity to restudy certain phases of the intestinal obstruction problem. The factors of bacterial infection and toxemia in the pathogenesis of death from experimental obstruction particularly were reinvestigated.

It is the purpose of this report to summarize our studies on the effect of penicillin in experimental types of intestinal obstruction and to show why the conclusions reached demand

new clinical emphasis on the phases of the problem which were investigated

PENICILLIN IN ISOLATED LOOP EXPERIMENTS

Prior to our experiments with penicillin in closed obstructed intestinal loops (12) it was known that animals with such lesions would die usually within a week after the creation of the loops in a manner which could best be explained on the basis of a toxemia. The pioneer studies of Stone, Bernheim and Whipple had demonstrated that death in such experiments could not be explained on a basis of vomiting and that septicemia was not a factor. The numerous experiments to prove or disprove the elaboration of toxic substances within isolated loops have been critically reviewed by Cooper (1928), Morton (1929) and Besser (1940). Some investigators, notably Davis and Stone, Murphy and Brooks, Dragstedt and Firor (10) believed that lethal toxins did develop in isolated loop experiments and furthermore that the source of these toxins was bacterial. This latter belief was based on a process of exclusion as there was no positive way to rule out sources other than bacteria for the production of toxins.

In Dragstedt's experiments the isolated loops were washed with ether. The dogs having washed loops survived much longer than did the controls. The possibility was never ruled out in his experiments that the ether might alter the loop mucosa thus interfering with the absorption of toxins of any origin. Firor (10) demonstrated with U shaped loops having both ends open at the surface of the dog's abdominal wall so that periodic through and through cleansing with saline solution could be accomplished that life was prolonged for considerable periods of time after the loops

From the Departments of Surgery and Pathology of the Johns Hopkins University and the Johns Hopkins Hospital.

Dr. Blain was formerly William Stewart Halsted Fellow in Surgery, The Johns Hopkins Hospital, now Resident Surgeon, The University Hospital, Ann Arbor, Michigan.

Presented in the forum on Fundamental Surgical Problems, before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

Fig. Occlusion of bowel lumen by transection just above termination of antimesenteric artery of ileum and closure of proximal and distal ends.

were finally closed. The fact that in his experiments the animals eventually died of inanition obscured the mechanism of death in these experiments but again suggested the elaboration of lethal toxins of bacterial origin.

Firor's original suggestion (11) that a modern chemotherapeutic agent (sulfasuxidine) be employed in isolated loop experiments, was, I believe, the greatest contribution to the study of intestinal obstruction since the introduction of the Miller Abbott tube by Abbott and Johnston. Firor and Poth (11) demonstrated that sulfasuxidine when placed in closed isolated loops, would protect animals with such obstructions for long periods of time. The work was confirmed (13). We had one such animal which was sacrificed over a year after operation. The objection to the sulfasuxidine experiments was that the mucosa was altered

by being covered with a thick paste which could theoretically have interfered with the absorption of toxins of any origin. The observations of Firor and Poth led to the important studies of Sarnoff and Poth (18) and Sarnoff and Fine (19) who reported that sulfasuxidine had a protective effect in dogs with ileal lesions, produced by occlusion of the mesenteric veins, but in which the bowel lumen was unobstructed. Their studies established the important rôle played by bacteria in such lesions, but showed that sulfasuxidine must be present for some time for effective bacterial depopulation of the bowel to occur.

In 1945 it was shown (12) with the use of penicillin either placed in isolated loops or administered parenterally in dogs having isolated loops, that bacteria or bacterial products were responsible for the death of animals in such experiments. Furthermore, the first dogs having isolated obstructed jejunal loops could be prolonged for significant periods of time when penicillin was placed in the loop or was given intramuscularly. Thus, in 0 per cent of 15 control dogs with isolated jejunal loops death occurred within $6\frac{1}{2}$ days; 81 per cent died in $3\frac{1}{2}$ days or less. In 100 per cent of 15 dogs, in whose isolated loops penicillin was placed protection was afforded for 9 days; in 93 per cent for 13 days and in 60 per cent for over a month. One hundred per cent of dogs treated parenterally with penicillin was protected for over 18 days. One dog lived over 2 months.

It was widely held at that time that penicillin was not effective against the gram negative bacilli. This study demonstrated that for all practical purposes, penicillin in large doses was effective *in vivo* against all the intestinal tract bacteria.

It was found that marked distention of the loop occurring in the presence of bacteriostatic agents was compatible with life. In the absence of distention of the loop, an abundant bacterial flora uninhibited by bacteriostatic agents was compatible with life. The experiments indicated that distention must be present before infection of the intestinal wall by the normal intestinal flora can occur. Microscopic and bacteriological evidence was presented to show that penicillin given properly

Fig. 2. Method of tying off mesenteric veins to ileal segment. a, Proximal turned in end b, distal turned in end c, rent in mesentery at distal extremity of segment to be strangulated. (Courtesy *Bull Johns Hopkins Hosp*)

lactically in large doses, whether in a loop or parenterally can prevent infection of the distended intestinal wall by the normal intestinal flora. Recently in experiments employing streptomycin in rabbits with closed loops (created by tying off the base of the large appendix) a similar protective action was demonstrated (9)

PENICILLIN IN STRANGULATED LOW ILEAL OBSTRUCTION

In an attempt to produce an obstruction more like that occurring in man and to test a treatment which might be effective for a similar type of obstruction in man Dr John D. Kennedy and the author (3) created strangulated low ileal obstruction in dogs by first completely occluding the bowel lumen (Fig. 1) and then tying off the mesenteric veins to a 60 centimeter segment of the obstructed bowel (Fig. 2). The resulting obstructions were characterized by severe strangulation (Fig. 3). The control dogs' intestines all showed mucosal ulceration and massive bacterial invasion superimposed on the venous infarction which would often be accompanied by perforation. In the first 24 hours following

the production of such lesions there would not always be peritonitis unless perforation had occurred. Later peritonitis developed whether or not there was perforation. The lesions in

Fig. 3. Strangulated low ileal obstruction showing gross appearance of the resulting hemorrhagic infarction of the bowel wall. The proximal turned-in end is in center of photograph. In this particular case this lesion was resected 72 hours after its production in a dog treated with massive doses of penicillin. The animal was cured.

Chart Diagram showing relative survival times of dogs with strangulated ileal obstructions not treated with penicillin as contrasted with the survival times of dogs with strangulated ileal obstructions treated with penicillin. It can be seen that 4 of the 5 penicillin treated dogs having late resections of the strangulated obstructions were

cured. Both groups are treated equally for hemorrhagic shock, chloride and water loss. Black, postoperative survival time of control dogs with strangulated ileal obstructions. Cross hatch, postoperative survival time of dogs with strangulated ileal obstructions, given massive doses of penicillin parenterally. Black dot, cures.

similar experimental obstructions which had been treated with massive doses of penicillin (100,000 units every 2 hours for 24 hours, 50,000 units every 2 hours during the next 48 hours, and 50,000 units every 4 hours during the remainder of the survival of these dogs whose weight averaged less than 16 kilo-

grams) always showed a well marked bacterial invasion microscopically but this was appreciably less than that which occurred in the controls.

Thirteen dogs, with this type of obstruction treated with whole blood and gelatin solution intravenously and with physiological

saline solution subcutaneously to combat hemorrhage, shock, chloride and water loss died within 36 hours. Seven dogs treated similarly but with massive doses of penicillin in addition survived between 50 and 100 hours (Chart 1). Six dogs lived 70 hours or longer 4 90 hours or longer. In addition in 2 other penicillin treated dogs resection of the strangulated obstructed bowel was performed at 72 hours (a period twice the survival of any control dog) with a cure in each animal. Later in 3 more penicillin treated dogs, resections were carried out at 72 hours, with cure in 2 of the 3 dogs. Thus, there were 5 late resections performed at a time which was twice as long as any dog not treated with penicillin lived. Four of the dogs in which late resections were performed were cured. Drs. Robert J. Calihan and Henry N. Harkins aided us in these latter experiments and we reported the resection experiments with them (4).

In all cases, the control dogs and the dogs treated with penicillin were treated with equal vigor for shock, hemorrhage, chloride and water loss. In 2 of the penicillin treated dogs and 1 of the controls, volvulus of the strangulated bowel converted simple strangulated obstructions into strangulated closed loop obstructions. Thus it was demonstrated that penicillin in the doses employed (which were massive) in the study, could prolong the lives of experimental animals having the type of strangulated obstruction chosen for the study. It was also demonstrated that this prolongation though striking was limited. Whether the limit was set by (1) the final inability of the penicillin in the doses employed to control bacterial infection (2) fatal alterations in metabolic processes and body chemistry (the serum NPN, phosphorus and potassium were elevated, the sodium and chloride were normal to high and the carbon dioxide combining power was low) (3) the presence within the peritoneal cavity of necrotic strangulated bowel, or (4) some combination of these factors, could not be definitely established on the basis of this study. Because of the effect of penicillin in experiments with nonstrangulated closed loops, however, it would appear that the effect of penicillin would be much more striking in obstruction in which the de-

gree or amount of strangulation was less marked.

These studies demonstrated that bacteria play an important rôle in the 'toxemia' and death in dogs with strangulated ileal obstructions and that aggressive antibacterial therapy in the form of frequent, massive doses of penicillin is effective to a significant extent in treating such lesions.

THE FIELD FOR PENICILLIN THERAPY IN HUMAN INTESTINAL OBSTRUCTION

In a study of 204 cases of acute complete mechanical obstruction of the small bowel, in which patients were operated upon at the Johns Hopkins Hospital during the 10-year period 1936-1945 there was an overall mortality of 20 per cent (5). When this mortality rate was corrected for deaths due to cardiac, pulmonary, and other causes not directly related to the intestinal obstruction the mortality rate was 15 per cent. Of the 41 deaths in the series, over half were due to peritonitis. In 27 per cent of all cases the bowel was strangulated at operation. In an additional 5 cases although the bowel was considered viable by the surgeon at operation gangrene and necrosis were found at autopsy. The strangulated cases accounted for over half of all the deaths due to peritonitis. The study confirmed the statement of McKittrick and Sarris that 'the factor of strangulation is the greatest single factor determining the outcome of a case of intestinal obstruction' and showed that there is a fertile field for an adjunct against bacterial infection in intestinal obstruction. Indeed it would seem that no further great reduction in the present mortality rate can be made until bacterial infection and 'toxemia' are combated.

DISCUSSION

Evidence has been presented which demonstrates the important rôle played by bacteria in death resulting from the types of obstruction studied. Furthermore it has been shown that the lethal effects of bacterial growth can be significantly obviated by massive doses of penicillin. It should be stated here that the exact mechanism by which bacteria produced their lethal effects in our experiments is not

clear. We feel that the ascribing of all deaths in experiments of this nature to peritonitis is an over-simplification of the problem (14). At any rate it would seem that the beneficial results of penicillin therapy noted in our experimental animals, could be applied directly to man. Human studies have revealed that the problems of strangulation and infection are grave ones and also that the presence of strangulation is often impossible to diagnose, especially in patients with early cases short of direct visualization of the affected bowel wall.

When these factors are combated in experimental animals life is prolonged and significant protection is afforded.

CONCLUSIONS

1. A clinical trial of massive antibacterial therapy for acute mechanical small bowel obstruction in man is warranted.

2. It is believed that such a trial would significantly lower the present intestinal obstruction mortality.

3. Penicillin should be regarded as an adjunct to early and adequate surgical intervention in acute obstruction and not as a means to delay operation.

THE changes which have come about in the surgical treatment of amputations due to the recent war effort and which are adaptable to use in civilian life have been chiefly the result of good planning and organization for the care of these cases. The early establishment of the use of sound surgical principles and practices for the early and immediate care and transportation of war amputations and implementation of these policies by authoritative directives was an important part of this planning. This together with the establishment and organization of special centers for definitive care and rehabilitation contributed more than anything else to whatever changes for the better there may have been in surgical treatment. The modern advances in medicine, medical education and graduate education played the rôle of making a higher standard of practice of medicine and surgery available, but all these would have amounted to very little had it not been for proper organization. (5) This brought the patients together under the direction of highly specialized surgeons who had the responsibility for not only organizing the whole functioning of the center with all its different departments but for all of the complete care of the whole patient and all of his problems. Even here in the amputation centers the value of organization could hardly be overestimated. For truly surgery is not the end but one of many means to the end in this field. Besides organization it was chiefly due to the fact that the surgeons were in complete charge of all of the amputee's problems from the time of his amputation until he was fitted with a limb and trained to use it that better surgery was done with better results than ever before. (1)

These are the important lessons learned from the War and herein lie the hints for the future if service is to be improved for civilians in the future. It is of course impossible and

unnecessary to duplicate the war services in civil life but it would be a simple matter indeed to establish organized amputation services in the larger civilian hospitals, just as fracture and other special services were developed in the past. The management of amputations would then improve just as fracture treatment has. There is no obvious reason why existing limb makers could not co-operate completely with the surgeons in this matter just as brace makers always have. There can be no quarrel between surgeons and limb makers. The ultimate aim of both should be to give the patient the best possible care. If either or both fail in this important task they may find someone else doing their work for them. For if something is not done to improve the care of civilian amputees the federal agencies may justifiably take over the whole problem including especially the manufacture and fitting of artificial limbs.

SURGERY

The strongest trend in the surgery of amputations has been toward more conservatism. This has been true both in the immediate surgical treatment and in the definitive surgery. The general use of the modified guillotine amputation at the lowest possible level resulted in the saving of more of the limb than ever before in war or civil life both at the time of primary amputation and finally when definitive surgery was done. The more complete understanding of the problem of the amputation stump in its relation to the prosthesis by the surgeons has resulted in a more conservative surgical attitude with a marked tendency to leave as much stump length as possible and to fit the remaining stump with a prosthesis regardless of its length. The chief exception to this is amputations below the knee of more than 7 inches in length. One of the truly great lessons learned was that the problems of the surgery of the stump are so closely related to those of the prosthesis that it is impossible to completely understand one without under-

standing the other and that they cannot be separated from one another. Since the surgeon is the only one who can understand all of the problems, particularly these two, he is the only one who is or ever will be qualified to properly supervise and direct the whole care of the amputation stump and the patient.

The important changes that have come about in the surgical treatment of amputations, then, have not been due to the development of new operations, techniques, or methods. Rather they are due to organization, good judgment, good surgery, and most important, the complete responsibility of surgeons for the whole patient and all of his problems. The problem is an arduous one and nothing has been found which will take the place of hard work and the greatest attention to details.

1. *The open or modified guillotine amputation.* The routine use of this method of amputation in the United States Army has again proved to be the safest and best method for use in war notwithstanding some opinions to the contrary. Although long skin flaps which tend to close the wound prematurely are undesirable, it is important that viable skin be conserved at least equal in length to the bone. The use of the modified guillotine amputation at the lowest level consistent with proper débridement without regard to the final site of amputation, with proper skin traction until the stump is ready for final revision or reamputation, has proved to be of such great value in the war that it must find greater use in contaminated civilian cases. The stump is ready for revision or reamputation in from 3 to 8 weeks post-operatively, depending upon the case. Reamputation at a higher level, when indicated, can be done much earlier than revision at or near the stump end. This is one of the reasons why the original open amputation should be done at the lowest possible level. The stump is ready for revision when the skin has been pulled well down over the stump end, drainage has ceased, swelling has subsided, and the remaining open wound is clean. Routine bacteriological examination of the stump wound is advisable before the final operation is done. It is not necessary or desirable in the majority of cases to wait for complete healing to take place (6).

The use of skin grafts on amputation stumps is mentioned only to be condemned. They are distinctly disadvantageous in that they stop the whole normal healing process and they are poor substitutes for the normal skin which can easily be drawn down over the stump-end by traction. When skin grafts are used they interfere with the function of the stump in the prosthesis by breaking down to such an extent that they should routinely be removed and traction applied until the skin can be closed. The removal of skin grafts from stumps for use elsewhere is equally to be condemned as the donor area causes difficulty when the prosthesis is applied.

2. *Essential points in amputation.* (a) The operation should be done with the use of a tourniquet whenever possible. The use of the tourniquet can be extended by the use of Wyeth pins on short thigh stumps.

b. Definitive operation should be done in a clean field and under careful aseptic precautions.

c. Except in end bearing stumps, the skin flaps should be cut equal in length so that they meet in the center of the end of the stump without redundancy. A general rule for estimation of the length of the skin flaps is to cut each flap approximately two-thirds of the length of the radius of the limb. The stretching of the flaps, which then results after under-cutting, permits them to lengthen sufficiently for closure.

d. The deep layer of fascia is reflected with the skin flap in primary amputation whenever possible. The muscles are divided slightly distal to the saw line so that after retraction has taken place the end of the muscles will be at the level of bone section.

e. The periosteum is sharply divided at the level of bone section.

f. The main nerves are gently pulled down, smoothly divided, and allowed to retract out of the stump end. Nerves are not ligated, cauterized, injected, or otherwise treated by any fancy technique.

g. The tourniquet should be removed after the main vessels have been ligated and complete hemostasis obtained. The skin flaps are closed by simple interrupted skin sutures. The use of subcutaneous and stay sutures is not

only unnecessary but contraindicated in that they further traumatize already ischemic flaps.

h Drainage should be used more or less routinely for 24 to 48 hours in all amputation stumps because of the tendency for postoperative drainage from the mass of sectioned muscle and from the bone.

3 *Postoperative care* There is no substitute for complete bed rest, elevation and proper splinting in amputations below the knee until complete wound healing has taken place. A period of at least 3 to 4 weeks is required for proper healing of these cases. Other amputations may heal in less time. Postoperative splinting is preferable to skin traction even in cases in which the skin flaps are tight. Amputations through, or above, the knee should not be elevated as this causes flexion contractures. These patients particularly bilateral above the knee amputees should be turned face down at intervals whenever possible to prevent contractures. The routine use of elastic bandages for compression dressings has been found to be of great value.

Exercises designed to overcome contractures and to strengthen the muscles of the stump are started as soon after wound healing as possible. Wrapping of the stump with elastic bandages for stump shrinkage when properly carried out has proved to be of great value. Exercises and wrapping are the only two forms of physiotherapy which are of value. Massage is always contraindicated as it may be harmful and is of no value.

Occupational therapy has proved to be important both in keeping the patient's mind occupied while he is waiting and also in the training of the use of the arm prosthesis.

4 *Extension grafts* The extension of the bone length of certain stumps when the normal soft tissues were present but were devoid of a considerable length of bone proved to be a practical and valuable procedure in certain cases particularly in amputations above the elbow. The fibula has been successfully used as an intramedullary extension graft in the medullary canal of the humerus.

The use of extension bone grafts on amputation stumps where any type of skin graft is required to extend the length of the stump is probably not justified in most cases in view of

the disappointing results obtained. This is true of arm stumps as well as various types of amputations of the hand, thumb and fingers.

5 *Homogenous bone and bone bank* The successful use of freshly transplanted homologous bone grafts in a number of patients with multiple injuries and amputations who had no bone graft donor site led to the limited use of a bone bank at the Thomas M. England General Hospital. The bone was collected from clean reamputations and stored in an ordinary electric refrigerator in glass jars containing normal saline solution saturated with sulfanilamide. The use of bone preserved in this manner was not great enough to warrant conclusions as to its value, but the experience was sufficient to suggest further experimentation with the method. This experience did prove beyond doubt that freshly transplanted homologous bone gave good final end results in a high percentage of the cases. These results will be published in a subsequent paper.

6 *Sulfa drugs and penicillin* The use of medication of this type has undoubtedly been helpful in combating serious infections and has saved time in some cases. The routine preoperative and postoperative use of medication of this type however has not been proved to be of outstanding value.

SITES OF MAJOR AMPUTATIONS

1 *Amputation of all digits at or near the metacarpophalangeal joints* Phalangization of the metacarpals, with complete removal of the second and third and sometimes the fourth metacarpal bones, and plastic closure of the remaining defect with the formation of a deep cleft was found to be the best solution to this problem type of amputation. The remaining digits thus formed have the advantage of sensation, active motion and prehension. They were so capable of function that all patients operated upon were completely satisfied with the results. The function thus obtained is in some ways similar to that of a Krukenberg stump. This type of stump is very satisfactorily fitted with a cosmetic hand which is used on occasions when active function of the stump is secondary to cosmetic appearance. The technique of this procedure will be described fully in a subsequent article.

Fig Sites of major amputations in upper extremity

2 *Amputation at the wrist joint* Amputation at the wrist joint has been revived both in this country and in Europe. The carpal bones should be conserved if possible, but if not disarticulation without them is satisfactory. Amputation at this site conserves length and when properly fitted with a prosthesis there is some useful pronation and supination. The prosthesis does not extend above the elbow. Amputation at the wrist is somewhat more difficult to fit with a prosthesis than amputation at the junction of the lower and middle third of the forearm but this can usually be overcome by effort and experience. There have already been many improvements in the prosthesis for amputations at the wrist both here and in England (4).

3 *Amputation at the junction of the lower and middle third of the forearm* If amputation through the wrist is impossible the next level of choice is at this level or approximately 2 inches above the styloid process. Before the war this was the standard site of amputation in the forearm and was preferred by most surgeons and limb fitters. All possible length should be saved above this level.

4 *Short below elbow stumps* All length possible should be saved below the elbow since improved methods of fitting have resulted in greater ability to fit these short stumps than ever before. It is possible to fit satisfactorily below the elbow stumps as short as one-half inch in length. The relative stump length may be slightly increased by resection of the biceps

tendon at the time of final operation. This can easily be done by reflecting the anterior flap without the necessity of making a separate incision (3a).

5 *Disarticulation of the elbow* Amputation at this level was found to be more useful than it had previously been thought to be. It is preferred to amputation at the supracondylar level wherever possible as it gives the stump longer leverage and when properly fitted the patient has better control of the prosthesis, particularly in performing internal and external rotation movements. The prosthesis is fitted with side joints and the type of prosthesis is similar in principle to that used for end bearing thigh stumps.

6 *Amputations at the supra-condylar level.* This is still the standard site of amputation above the elbow. The supracondylar amputation should be left as long as possible. The site of bone section is immediately above the condyles of the humerus. Above this level all possible stump length should be saved.

7 *Short above elbow stumps* A stump at least 2 inches in length below the axillary fold is necessary for the active use of a prosthesis. If the stump is shorter all possible bone should be saved including the head and neck of the humerus, despite the fact that amputations at this level will be fitted as disarticulations of the shoulder. Attempts to increase the relative length by section of muscles and tendons have proved disappointing.

8 *Disarticulation of the shoulder* Disarticulation of the shoulder should never be performed except where surgically necessary. The head and neck of the humerus should be conserved wherever possible for contour and normal appearance. This surgical conservatism also results in better prosthetic fitting and improved prosthetic accomplishment.

SPECIAL METHODS FOR USE IN UPPER EXTREMITY¹

The Krukenberg operation (or stump) The Krukenberg method consists of surgical separation and phalangization of the radius and

¹The basis for the statements used in connection with the Krukenberg and diaphasic methods was personal observation at the American Occupied Zone in Germany, where the author was member of the Army Surgeon General's European Commission on Amputations and Artificial Limbs (1946).

ulna so that the resulting claw shaped stump is capable of some prehension and has the advantage of sensation. The use of this procedure is limited to amputations below the elbow of at least 11 centimeters in length from the lateral epicondyle. Although the method has been widely used in Germany particularly on bilateral amputees with or without eyesight, it probably would not meet with general acceptance in this country. The use of the Krukenberg method however, should be valuable in the surgical treatment and rehabilitation of all blind bilateral amputees.

The cineplastic method The only form of cineplasty still in use is the muscle tunnel type of Sauerbruch. It is still widely used by some surgeons in Germany and the surgical technique has recently been improved considerably. The use of this method has been limited in this country and discontinued in most others chiefly because of inadequate prosthetic facilities. There has recently been considerable renewed interest in cineplasty but extensive use of the method must await further prosthetic research and development which is being carried on by the Committee on Artificial Limbs of the National Research Council. When this work has been completed the method may well be subjected to more extensive trial use when its true value in this country can be finally determined.

LOWER EXTREMITY

1 Amputations through the foot Partial amputations of the foot up to the Chopart level can usually be fitted with shoe corrections and appliances so that they will give very satisfactory function. One of the important lessons learned in the recent War was that the Chopart amputation could not usually be fitted with anything in the way of a shoe correction or a prosthesis which was satisfactory. The Syme amputation is therefore almost always preferable to the Chopart. Much time worry and dissatisfaction can be prevented on the part of the patient and surgeon by the early and immediate application of the Syme amputation to almost all of these cases. Attempts to improve the function of the Chopart amputation by subastragalar and ankle joint fusion have usually been unsuccessful.

Fig. 2 Sites of major amputations in lower extremity

Center of knee joint is the center of axial motion which is located in the center of the femoral condyle, $3\frac{1}{2}$ inch above the joint line.

2 The Syme amputation The Syme amputation when properly performed under the proper circumstances is preferable to any other major amputation in the lower extremity. It is the only amputation recommended at the ankle. The use of amputation at the ankle was greatly revived in this country during the recent war although it had previously been used only to be generally forgotten. Details concerning the Syme amputation during the War have been published in two previous articles (2, 3).

3 Amputations below the knee Although amputations in the lower third of the leg above the Syme level may be satisfactory in some cases they are not generally favored, because of poor circulation. The ideal level of amputation below the knee is generally accepted to be five to seven inches below the knee joint. Most surgeons, who have had the greatest experience, prefer a length of not over 5 to $5\frac{1}{2}$ inches below the knee joint. The use of partial or complete ischial weight bearing has been found to be useful in fitting many imperfect below the knee stumps.

4. Short below the knee stumps The fibula should be completely removed in all below the knee stumps shorter than $3\frac{1}{2}$ inches and these may be fitted as short as $1\frac{1}{2}$ inches below the knee joint if the leg is not too fleshy. Success in fitting these short stumps depends upon the proportion of length to width. Stumps with little soft tissue covering there

fore are more favorable at this level. Some of these short stumps are advantageously fitted with considerable end weight bearing. Section of the hamstring tendons may give additional relative length to the stump in some cases (3a).

5 *The flexed leg stump (bent knee)* Below the knee stumps, which have for any reason definitely proved to be unsatisfactory or are too short for fitting as below knee stumps, may be flexed to 90 degrees and fitted very satisfactorily with a prosthesis with full weight bearing on the bent knee. If sufficient stump length projects posteriorly in this type of fitting it has the advantage of full end bearing without the necessity of any type of belt or suspenders for suspension of the limb. This is one of the oldest methods of prosthetic fitting in the lower extremity the use of which has been revived in the War.

6 *Disarticulation of the knee* Amputations at this site may give excellent results in some cases. It is important that the greatest care be exercised in performing amputations at this level. Unless good healing and full end bearing are obtained the results may be disappointing.

The patella is left in position without removal of the cartilage unless more length is desired in the anterior flap. Removal of the patella in such cases may result in considerable additional relative length of the anterior flap. The cartilage of the femoral condyles is not removed. It is important that the hamstring muscles be sutured to the patella tendon in the intercondylar notch to prevent separation of the skin flaps. When properly fitted with a prosthesis most of these cases need no pelvic or shoulder suspension of the limb since accurate fitting of the socket to the bulbous end of the stump secures it in place.

7 *Supracondylar amputation of the thigh* The supracondylar tendoplastic amputation apparently gives equally as good results as the Gritti-Stokes. The only difference in these two amputations is that the patella is excised in the supracondylar tendoplastic procedure, whereas it is fixed to the end of the femur in the Gritti Stokes. The supracondylar tendoplastic amputation has the advantage of being

a simpler surgical procedure than the Gritti Stokes. The former was more commonly used in the Army amputation centers than the latter.

8 *Amputations above the knee* In amputations above the supracondylar Gritti-Stokes level the end of the stump should not be longer than 3 inches above the center of the knee joint.¹ Many surgeons of great experience prefer an ideal length of not over ten to twelve inches from the trochanter. If amputations of the thigh are longer than 3 inches above the center of the knee joint, it will be necessary for the prosthetic maker to make the thigh piece longer than the normal thigh, and the shun piece shorter than normal so that the knee joint of the artificial limb can be incorporated. All possible length should be saved above this level.

9 *Short above the knee stumps* It is possible for above the knee stumps as short as 2 inches, measured from the crotch to be fitted as above the knee amputations. Here again this depends somewhat on the proportion of length to width the thinner ones being preferable. If a short thigh stump proves to be too short to be fitted as an above the knee amputation it may be fitted with a tilting table as a hip joint disarticulation when the stump is flexed to 90 degrees. The head, neck, and trochanter should never be removed except when absolutely necessary as the presence of this structure helps to stabilize the prosthesis and it conserves the normal contour of the pelvis.

ADVANCES IN BONE GRAFT SURGERY ATTRIBUTED TO WORLD WAR II

GEORGE K. CARPENTER, M D F A C S Nashville, Tennessee

BONE graft surgery as performed by the military surgeons during the early months of World War II was little different from that performed in civilian life. Sound civilian surgery became good military surgery. The advances derived from war experience should now be applied to present day civilian practice.

Experience has shown that better end results are obtained when both the patient as a whole and his extremity are effectively prepared for bone graft surgery. The patient's general condition should be at its best prior to surgery. Blood transfusions are often indispensable in rendering the patient in optimum condition for surgery. It has been well shown by Brown Shaw, Mech and others that existing scar tissue must be appropriately treated prior to bone graft surgery. Once nonunion is accepted, the extremity is subjected to a well supervised preoperative program of physical therapy which is outlined to improve circulation and muscle tone and to mobilize the joints.

Presented in the symposium on Fractures and their Trauma before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

Chemotherapy plays an important rôle in bone graft surgery. This is particularly true since nonunion so frequently follows a compound fracture. Chemotherapy will not permit bone graft surgery in the presence of infection. It is our practice to delay bone graft surgery until approximately 3 months following complete wound healing. The time interval between complete wound healing and bone grafting may vary somewhat depending upon the character and duration of the infection but it is safer for the patient if the surgeon waits longer than was necessary rather than to operate too early. It is our practice to employ adequate penicillin therapy for 2 days prior to surgery and for approximately 5 days following surgery.

It is believed that nonunion is too often not recognized and accepted in an early stage and as a consequence bone grafting is frequently unnecessarily delayed. So called delayed union usually progresses to nonunion. To treat delayed union for 3 months and at the end of this time find that bone graft surgery is necessary is most time consuming to the patient. Prolonged immobilization is detrimental to restoration of function. The morbidity of a

Fig 1

Fig 2

Fig 2 Case 1: Three and a half months after bone graft with iliac bone

fore, are more favorable at this level. Some of these short stumps are advantageously fitted with considerable end weight bearing. Section of the hamstring tendons may give additional relative length to the stump in some cases (3a).

5 *The flexed leg stump (bent knee)* Below the knee stumps, which have for any reason definitely proved to be unsatisfactory or are too short for fitting as below knee stumps, may be flexed to 90 degrees and fitted very satisfactorily with a prosthesis with full weight bearing on the bent knee. If sufficient stump length projects posteriorly in this type of fitting it has the advantage of full end bearing without the necessity of any type of belt or suspenders for suspension of the limb. This is one of the oldest methods of prosthetic fitting in the lower extremity, the use of which has been revived in the War.

6 *Disarticulation of the knee* Amputations at this site may give excellent results in some cases. It is important that the greatest care be exercised in performing amputations at this level. Unless good healing and full end bearing are obtained, the results may be disappointing.

The patella is left in position without removal of the cartilage unless more length is desired in the anterior flap. Removal of the patella in such cases may result in considerable additional relative length of the anterior flap. The cartilage of the femoral condyles is not removed. It is important that the hamstring muscles be sutured to the patella tendon in the intercondylar notch to prevent separation of the skin flaps. When properly fitted with a prosthesis, most of these cases need no pelvic or shoulder suspension of the limb, since accurate fitting of the socket to the bulbous end of the stump secures it in place.

7 *Supracondylar amputation of the thigh* The supracondylar tendoplastic amputation apparently gives equally as good results as the Gritti Stokes. The only difference in these two amputations is that the patella is excised in the supracondylar tendoplastic procedure, whereas it is fixed to the end of the femur in the Gritti Stokes. The supracondylar tendoplastic amputation has the advantage of being

a simpler surgical procedure than the Gritti Stokes. The former was more commonly used in the Army amputation centers than the latter.

8 *Amputations above the knee* In amputations above the supracondylar Gritti-Stokes level the end of the stump should not be longer than 3 inches above the center of the knee joint.¹ Many surgeons of great experience prefer an ideal length of not over ten to twelve inches from the trochanter. If amputations of the thigh are longer than 3 inches above the center of the knee joint it will be necessary for the prosthetic maker to make the thigh piece longer than the normal thigh, and the shin piece shorter than normal so that the knee joint of the artificial limb can be incorporated. All possible length should be saved above this level.

9 *Short above the knee stumps* It is possible for above the knee stumps as short as 2 inches, measured from the crotch, to be fitted as above the knee amputations. Here again this depends somewhat on the proportion of length to width, the thinner ones being preferable. If a short thigh stump proves to be too short to be fitted as an above the knee amputation it may be fitted with a tilting table as a hip joint disarticulation when the stump is flexed to 90 degrees. The head, neck, and trochanter should never be removed except when absolutely necessary, as the presence of this structure helps to stabilize the prosthesis and it conserves the normal contour of the pelvis.

ADVANCES IN BONE GRAFT SURGERY ATTRIBUTED TO WORLD WAR II

GEORGE K. CARPENTER, M D F.A.C.S Nashville, Tennessee

BONE graft surgery as performed by the military surgeons during the early months of World War II was little different from that performed in civilian life. Sound civilian surgery became good military surgery. The advances derived from war experience should now be applied to present day civilian practice.

Experience has shown that better end results are obtained when both the patient as a whole and his extremity are effectively prepared for bone graft surgery. The patient's general condition should be at its best prior to surgery. Blood transfusions are often indispensable in rendering the patient in optimum condition for surgery. It has been well shown by Brown Shaw, Mech and others that existing scar tissue must be appropriately treated prior to bone graft surgery. Once nonunion is accepted, the extremity is subjected to a well supervised preoperative program of physical therapy which is outlined to improve circulation and muscle tone and to mobilize the joints.

Presented in the symposium on Fractures and other Trauma before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 16-20, 1946.

Chemotherapy plays an important rôle in bone graft surgery. This is particularly true since nonunion so frequently follows a compound fracture. Chemotherapy will not permit bone graft surgery in the presence of infection. It is our practice to delay bone graft surgery until approximately 3 months following complete wound healing. The time interval between complete wound healing and bone grafting may vary somewhat, depending upon the character and duration of the infection but it is safer for the patient if the surgeon waits longer than was necessary rather than to operate too early. It is our practice to employ adequate penicillin therapy for 2 days prior to surgery and for approximately 5 days following surgery.

It is believed that nonunion is too often not recognized and accepted in an early stage and as a consequence bone grafting is frequently unnecessarily delayed. So called delayed union usually progresses to nonunion. To treat delayed union for 3 months and at the end of this time find that bone graft surgery is necessary is most time-consuming to the patient. Prolonged immobilization is detrimental to restoration of function. The morbidity of a

Fig. 3. Case 2. Nonunion 5 months following injury.
Fig. 4. Case 2. Three months following iliac crest bone graft.

fracture is in direct proportion to the extent and duration of the disability and its associated economic sequelae.

In cases in which the surgeon is reasonably assured that nonunion is inevitable bone grafting should not be delayed except as is necessary to fulfill the usual prerequisites for bone graft surgery. Unless the surgeon is reasonably assured that so called delayed union will soon progress to solid bone union it is believed that bone grafting should be performed without delay. Carpenter

Fig. 5.

Fig. 6.

Fig. 5. Case 3. Nonunion 5 months following severe compound fracture.

Fig. 6. Case 3. 7 months following onlay graft.

Rosenfeld and Mech have described the treatment of limited union by reinforcement bone grafts as a procedure planned to shorten the time needed to obtain a bony union of sufficient size and strength to permit early and unprotected function of the extremity. This treatment of limited union decreases the disability and thereby reduces the morbidity of the fracture.

A patient with nonunion requires a careful consideration of the individual problem at hand and a method of procedure is planned which will assure the maximum of function in the minimum of time. Needless to state, the

Fig. 7.

procedure of choice must be a safe one for the patient, and this will necessitate sound surgical judgment and respectful understanding of morbidity. Cancellous bone such as that obtained from the wing of the ilium offers exceptional qualifications as the graft of choice. It is ideal for a spinal or sacroiliac fusion and in nearly all joint fusions which necessitate the use of autogenous bone. Unfortunately the usual bone graft operation for nonunion is performed with the patient on his back, and since the posterior wing of the ilium presents the better donor site, certain technical difficulties most often make the ilium an impractical site from which to obtain the grafts. Adequate internal fixation of the fracture site is very advantageous and can be better obtained by the application of an onlay graft with screw fixation. Cancellous bone in lesser quantities can, of course, be obtained from the tibia. The tibia serves as the best donor site in the majority of cases. Multiple chip grafts as can be obtained from the tibia, also serve to stimulate osteogenesis.

The long bones may be better grafted by the application of long tibial grafts with cancellous bone and chips packed about the fracture site and along the graft. Two to four screws will as a rule adequately maintain in

ternal fixation of the fracture and graft. Frequently in nonunion of the femur the fracture is fixed by the application of a six screw metallic plate to facilitate postoperative treatment in a Thomas splint and a Pearson attachment traction apparatus. Nonunion of the femur thus treated by the application of a metallic plate in addition to a tibial graft and cancellous bone eliminates the use of plaster and permits early knee motion. Although it is believed that positive fixation of the fracture and of the graft very materially hastens the union, such treatment is not always employed.

Fig. 15. Case 8. Two and a half months after fracture of femur.

Figs. 16 and 17. Case 8. Five months after onlay graft and plate.

As a general rule plates and screws are used sparingly. If at all in treating a case of nonunion which previously showed infection even though wound healing had been complete for at least 3 months. Bones well covered with muscles, such as the shaft of the humerus and femur will tolerate plates and screws much better than such locations as the lower third of the tibia. The site of the nonunion should be cleared of scar tissue and sclerotic bone, but when extensive infection has been present, it may be unwise to treat the fracture site. An onlay graft may be reasonably expected to take without performing an extensive resection of scar tissue and sclerotic bone. A sliding inlay graft is an excellent procedure for treatment of nonunion of the tibia following a simple fracture but when nonunion follows a compound fracture of the lower third of the shaft of the tibia an onlay graft, without screw fixation is applied to the lateral aspect of the tibia. Intermedullary grafts are rarely if ever used. With loss of substance multiple grafts with much cancellous bone and chips are employed in an effort to restore the bone to its normal size. It is imperative that plenty of bone be used in every case. The surgeon must be ingenious and resourceful and an exponent of sound surgical principles.

SUMMARY

The advances in bone graft surgery emanating from the experiences of World War II which are equally applicable to civilian practice are briefly as follows

1. A full appreciation of the value of rendering the patient in optimum condition for surgery and maintaining his blood and nutritional requirements throughout the convalescence, as so well described by Lyons.

2. Like the patient as a whole, the extremity itself is likewise put in optimum condition for surgery.

3. Chemotherapy will permit the infected compound fracture with nonunion to be grafted earlier but never until the elapse of an adequate time interval following complete wound healing.

4. An early recognition of nonunion will permit grafting as soon as the usual prerequisites for bone graft surgery are satisfied.

5. Adequate internal fixation of the fracture and of the graft preferably by using screws and a tibial graft seems to stimulate the osteogenic activities of the graft and is desirable except when the site of fracture was previously the seat of an extensive infection.

FRACTURE OF THE CARPAL SCAPHOID

MATHER CLEVELAND M D F.A.C.S New York, New York

THE navicular of the hand is invariably called the scaphoid by those who write of its pathologic state. Oblitz and Halbsteln (1) described the nutrient foramina on which the blood supply of this bone depends. The largest and most numerous of these foramina are distal to the constricted portion called the waist by clinicians. These writers concluded that a complete fracture at the waist would seriously interfere with the blood supply of the proximal fragment in about a third of the cases. *This is the important factor in the healing of these fractures.*

Mechanism These fractures are due to indirect violence transmitted from the outstretched hand along the radial axis of the hand and forearm. These radial axis injuries are in order of sequence but not frequency as follows (1) fracture of the first metacarpal bone (2) fracture of the greater multangular bone, (3) fracture of the carpal scaphoid (4) perilunate posterior dislocation of the carpus (5) Colles fracture (6) fracture of the head of the radius. These lesions occur separately and in combination (Fig 1 and Fig 2). In the younger age group such as we had to deal with in the armed forces whose strong muscles resist the indirect violence fracture of the carpal scaphoid occurs 4 to 5 times as frequently as Colles fracture. In the more elderly with flabby muscles the wrist immediately extends and Colles fractures predominate.

Clinical recognition of the fracture If after a fall on the outstretched hand or similar trauma, the patient complains of pain at the radial side of the carpus, inability to grasp firmly, and shows no obvious deformity but constant, definite tenderness in the interval between the long and short extensor tendons of the thumb a fracture of the carpal scaphoid should be assumed to exist until its absence is proved by roentgenogram.

Presented to the symposium on Fractures before the Clinical Congress of the American College of Surgeons, Cleveland Ohio December 16-20, 1946.

Roentgenography The use of the roentgenogram as an aid to diagnosis in a very high percentage of wrist injuries led to the discovery of an enormous number of these carpal scaphoid fractures in the armed forces. A complete or widely displaced fracture may be immediately revealed by the first roentgenogram in conventional positions. At times the first roentgenogram will fail to reveal the fracture which will be readily seen 2 weeks later due to absorption at the fracture line. Those views which show this fracture to best advantage are (1) an anteroposterior with the hand in marked ulnar deviation and (2) a postero-anterior in 45 degree angle oblique projection.

The fracture A few of these fractures occur at the tuberosity where the transverse carpal ligament is attached. These avulsion fractures heal uneventfully in short order.

The fracture under consideration occurs at the waist and heals according to the blood supply which remains to the proximal fragment. Fractures with an adequate blood supply to the proximal fragment should heal with 8 to 10 weeks of immobilization while those with an

This soldier was disabled 3 months, at least 8 months longer than necessary because his injury was unrecognized.

Fig. 2. Pvt. H.L.B. Jeep accident November 6, 1945, France. Injuries recognized and treated immediately. a, at left, Roentgenogram of right wrist showing perilunate dislocation with a complete badly separated fracture of the scaphoid. b, at right, Roentgenogram of left wrist on day of injury showing fractures of greater multangular, carpal scaphoid and Colles. b, at left, Roentgenogram of right wrist July 30, 1946, 8 months after injury. Dislocation reduced, scaphoid fracture ununited. a, at right, Roentgenogram of left wrist July 30, 1946, 8 months after injury. Fracture of greater multangular and Colles are united. Carpal scaphoid ununited. This case is shown as bilateral carpal scaphoid fracture with three other associated radial axis injuries in the two wrists. This soldier refused further treatment, stated that his symptoms were minimal. He could do his civilian job and requested discharge from the service.

inadequate blood supply will require up to 20 weeks or longer before healing ensues. Unfortunately there is no means of determining in advance into which group any given fracture of the scaphoid falls.

TREATMENT

Treatment of the fracture is by prompt immobilization of the wrist in a glove type circular plaster splint extending from just below the elbow to the distal palmar flexion crease, allowing full motion in the fingers. The wrist is in slight dorsal flexion. The thumb is usually immobilized in anatomic position beyond the distal joint. Various positions of the thumb have been advocated with equally good results reported. This does not appear to be a vital factor.

Since no complete fracture of the carpal scaphoid through the waist heals in much less than 8 weeks, plaster immobilization should be continuous for this period. The plaster splint is then bivalved, a roentgenogram is

taken, and the splint immediately reapplied. If the fracture is united the splint is discarded. If union of the fracture is doubtful a new circular plaster splint is promptly applied. If this roentgenogram reveals the proximal fragment with its original density while the distal fragment shows atrophy, there is definite evidence of interference with blood supply to the proximal fragment, and prolonged immobilization of the wrist up to 20 weeks or longer may be indicated.

RESULTS OF TREATMENT

Shands reported that 195 of 198 carpal scaphoid fractures treated by trained orthopedic surgeons in 6 Army Air Force hospitals resulted in union an incidence of 98.5 per cent. Oblatz (2) reported in greater detail a series of 28 carpal scaphoid fractures from an Army Ground Force Hospital. He personally

followed these cases until plaster splints could be discarded. Union occurred in every case without aseptic necrosis in a single instance.

These 2 instances are, of course, optimum results obtained by experts. Experience gained by the medical officers of the armed forces offers to civilian surgery two salient facts about this fracture: (1) it is a common injury; (2) with complete knowledge of the problem and proper treatment based on that knowledge, a high percentage of those fractures will heal.

Beware of a diagnosis of sprain of the wrist joint¹ (Fig. 3.)

MANAGEMENT OF COMPOUND FRACTURES IN THEIR EARLY PHASES

OSCAR P. HAMPTON, Jr. M.D. F.A.C.S. St. Louis, Missouri

THE advances during World War II in the management of compound fractures in their early phases came not only in improved techniques of excisional surgery in forward hospitals and in the broad application of specific procedures such as delayed closure of the compounding wounds and surgical incisions or delayed internal fixation of malaligned compound fractures several days later in base hospitals, but of greater importance in a change of concept for the management of these wounds. Moreover the basic principles of the science of surgery itself were irrevocably reaffirmed.

Battle received compound fractures were all compounded from without in and were potentially septic because of the usually present extensive soft part and bone damage, the mud clothing and other foreign material often buried deep in the wound and the prolonged time lag from wounding to surgery. The wounds and incisions of initial surgery of necessity remained unsutured and reduction of the fractures was usually delayed 5 to 10 days until the wounded men had been transferred to base hospitals. The comparable lesions in civilian life, then, are injuries many hours or days old

with unreduced fractures and open and possibly grossly septic wounds.

In the early experience, The Orr Trueta regimen of closed plaster subsequent to débridement had in general left much to be desired. Slow wound healing by granulation with heavy scar formation was accepted, prolonged wound suppuration with necrosis of living tissue was not infrequent, inadequate reduction of fractures anticipating malunion or nonunion was often accepted, and the prolonged plaster fixation predisposed to extreme muscle atrophy and fixation of joints. Fear of stirring up and establishing limb or life endangering sepsis including gas gangrene had prevented efforts at delayed wound closure, at delayed open reduction and internal fixation of unreduced fractures, and even at radical secondary débridement to combat sepsis, the therapy of which had included only prolonged drainage through the open wound, local and systemic sulfonamide in an effort to control the bacterial flora of the wound and immobilization.

Based upon previous experiences and observations, during the Cassino and Anzio impasse in early 1944 and the later offensive attendant to the Fall of Rome, the closed plaster—open wound—fear of surgery in a septic field concept was discarded in favor of that of repair

From Department of Surgery, Washington University.

Traction is being made on a wire through the tibial tubercle while vertical lift is being made on the distal femoral fragment by means of a second wire through this fragment.

tive surgery of compound fractures. The new regimen included aggressive secondary surgery in the several days old and possibly septic wound with delayed excision of dead tissue if necessary, internal fixation of fractures on precise indications and partial or complete closure of clinically clean compounding wounds with obliteration or dependent drainage of residual dead space. Penicillin therapy systemically was employed as a safe guard against invasive infection of living tissue by the bacterial flora of the open wound. It was used as a means to a better surgical result and not in an attempt to sterilize an open wound. Whole blood replacement therapy was used extensively to permit prolonged anesthesia and surgery as an aid in the prevention of chronic sepsis and presumably as an aid to wound healing.

The concept for the newer regimen may be stated as follows:

'Wound sepsis results from the septic decomposition of dead tissue including blood clot in dead space. If a wound is free of dead tissue and if dead space is obliterated or dependently drained and if living tissue is protected from invasive infection by an effective

antibacterial agent the bacterial flora of an open wound may be disregarded and any reparative procedure may be performed within the range of recognized surgical limitations without fear of sepsis and with the anticipation of good wound healing.'

The experiences and successes achieved in the application of this concept in the management of unreduced compound fractures with open wounds several days after the initial surgery permit the following conclusions. The supporting data, mostly have been published.

1 In the prevention or eradication of wound sepsis, regardless of the time lag since injury or duration of sepsis, the surgical excision of dead and devitalized tissue and the obliteration or dependent drainage of dead space are prime considerations. Devitalized tissue is the forerunner of sepsis and when sepsis intervenes, reparative measures are doomed to failure, delayed or nonunion of the fracture may follow and wound healing will be postponed or prevented. Hence the importance of thorough initial surgery in preparation for reparative surgery several days later.

2 Delayed closure of clinically clean wounds that is wounds free of dead tissue and débris

MANAGEMENT OF COMPOUND FRACTURES IN THEIR EARLY PHASES

OSCAR P HAMPTON Jr MD F.A.C.S. St Louis, Missouri

THE advances during World War II in the management of compound fractures in their early phases came not only in improved techniques of excisional surgery in forward hospitals and in the broad application of specific procedures such as delayed closure of the compounding wounds and surgical incisions or delayed internal fixation of malaligned compound fractures several days later in base hospitals, but of greater importance, in a change of concept for the management of these wounds. judicious application of these principles that is, the excision of dead tissue when and wherever it is found obliteration or dependent drainage of dead space staged closure of wounds, atraumatic technique with fine hemostats and fine ligatures pressure dressings adequate reduction and immobilization of fractures, and precise splinting and with the

adjuvant use of penicillin and whole blood the objectives of the regimen were achieved. Surely the same regimen under the same principles is applicable to many compound fractures of civilian life which are seen many hours days or weeks after injury has occurred and particularly to those with established sepsis.

OSTEOMYELITIS FOLLOWING COMPOUND FRACTURES

GROVER C PENBERTHY M.D. F.A.C.S. Detroit Michigan

THE changes which have been brought about in civilian practice with respect to osteomyelitis complicating compound fractures have resulted from the application of sound surgical principles and careful attention to detail. Many believe that the advances made in the treatment of these cases are the result of sulfonamides and penicillin. This is not wholly true for while the antibiotics have played an important part good surgical care has been of paramount importance. Antibiotics are best applied systematically and there can be no doubt that a patient in poor general condition does not respond as well to these agents in combating infection as one in a good state of health. In patients who have had acute blood loss or with hemoglobin values low because of long continued infection, it is necessary to give adequate blood transfusions if antibiotics are to be of value.

A debilitated patient is a good host for bacteria. A healthy one resists invasion by organisms. Compound fractures are severe open wounds. The fundamental principles underlying open wounds apply whether the bone is involved or not. The realization and adoption of these principles have resulted from experiences in World War II. Wounds seen early carefully cleansed of as many contaminating organisms and foreign bodies as is possible and

the devitalized tissue carefully debrided are best closed primarily. If this seems not feasible secondary closure (1) of the wound after several days is advisable. If large defects in the skin or soft tissue result immediate skin grafts assist the wound to heal kindly even though they may need replacing later with a full thickness sliding or pedicle graft. Obviously good principles of fracture and wound care must include immobilization. This can and should when possible, be accomplished without the use of screws or plates. Large dead spaces must be obliterated (3) and when this is not possible dependent drainage must be afforded to minimize the complication of osteomyelitis.

Chronic osteomyelitis resulting from compound fracture actually is less frequent today than it was before the war because these principles mentioned above have been more widely recognized as a result of the experiences of World War II. The best treatment for this condition is prevention and careful attention to principles of care of wounds. This is the best prophylaxis we have.

Chronic osteomyelitis should not be confused with hematogenous osteomyelitis which presents an entirely different problem. The two conditions are separate entities and have different clinical pathological radiological and surgical considerations. Unlike hematogenous osteomyelitis this type practically never metastasizes but remains an infection within the bone locally. The treatment of es

Fig. 3 a, Anteroposterior and lateral view of a comminuted fracture of the femur which is the site of a gas abscess. The patient had been wounded by a high explosive shell fragment 10 days previously and had received inadequate excisional surgery. Local and systemic sepsis had followed. Although the gas abscess is visible on the roentgenogram, there were no clinical signs of gas gangrene. b, The gas abscess was drained and devitalized tissue was excised through a long posterolateral incision. The dead space about the fracture site was obliterated by fixing the fragments in apposition by means of a six hole bone plate. This illustration shows the fracture partially united 3

months after drainage of the abscess and concurrent plating of the fracture. The wound had been healed since about 3 weeks after the internal fixation of the fracture. c, The wound remained healed and the fracture firmly united in anatomical alignment. Because of some absorption about the screw as visualized on roentgenograms, the plate and screws were prophylactically removed with immediate closure of the wound and primary healing. d, This illustration reveals the completely healed wound of the thigh (its some excessive scar formation which required later excision and subsequent repair). This result is a triumph for the principles of reparative surgery.

and of signs of invasive infection is surgically sound provided dead space is obliterated or dependently drained and excessive tension is avoided. The sliding or advancement of flaps to permit closure without tension is often worthwhile. Therefore given a clinically clean compounding wound several days after excisional surgery wound healing by granulation should be scorned and if surgical limitations do not preclude, wound closure by suture or skin graft should be performed. Wound healing while affected by several factors, is a natural cellular growth provided the wound does not contain dead tissue, dead space, strangulating ligatures, etc. Wound closure may be practiced to the extent to which these qualifying factors can be surgically obviated.

3 The best evidence of adequate excisional surgery is a clinically clean wound 5 days later the optimum time for delayed wound closure. Within this period excellent drainage of wound exudate and residual debris is provided, and closure of wounds before the formation of heavy granulation tissue and reduction of fractures before the fixation of fragment ends are permitted.

4 Despite an unhealed wound inadequate reduction of fractures need not be accepted if it is preventable by open reduction with or without internal fixation. Reduction of the fracture eliminates the dead space about malaligned fragment ends, avoids subsequent manipulations which may produce additional devitalized tissue and anticipates minimum deformity. Internal fixation is detrimental to wound healing only as devitalized tissue is created in its application or as it interferes with soft part coverage of denuded bone.

5 The regimen as a whole may be expected to achieve minimum sepsis, rapid healing of wounds with minimum scar, maximum reduction of fractures, and maximum functional restoration of the extremity. In this experience no loss of limb or life attributable to the aggressive surgery was reported.

In summary reparative surgery of compound fractures represented a major advance in World War II. Under its principles, the spotlight was moved from the bacterial flora to the pathology of the open wound and a surgical approach was established for the management of septic compound fractures. By

APPLIED ANATOMY IN EYE SURGERY

MEYER WIENER, M.D. F.A.C.S. Coronado California

APPPLIED anatomy serves a twofold purpose. It gives a precise basis to those occurrences and procedures that especially involve anatomical knowledge, and, in addition, it converts an otherwise unusually dull subject into one of interest by associating it with something manifestly useful and practical.

The student of anatomy has a somewhat hazy fanciful notion that his study of anatomical structure will, in some way and at some future time prove useful to him. By incorporating with it its surgical application he is made aware of its value in very much the same way as a series of experiments in laboratory physics relates to sheer theoretical, scientific data.

While it is assumed that eye surgeons, in general, are acquainted with most of the premises which I am presenting it is with the hope that the memory of the dissecting days which have been growing a bit gray with some of us will wish to recall some of the anatomical matters which have the most direct bearing on surgical practice.

In surgery of the lids we must constantly bear in mind the delicate nature of the skin as well as the changes which come with advancing years which have a direct connection with surgical performance. The skin of the eyelid is the most delicate in the body pale and loosely attached. The foreskin approaches it most nearly in texture. However, it is not wise to use foreskin for lid replacement because, for some unknown reason, it nearly always becomes deeply pigmented. If not much is needed, the skin of the opposite lid is ideal if available. Probably next in order is that just back of the ear or that from the inside of the arm.

In old age the skin atrophies and loses its elasticity due to atrophy of the elastic fibers. This sometimes induces spastic entropion since the overaction of the orbicularis has no

resilient skin to overcome it. The Ziegler cautery is effective by causing the skin corresponding to the lower margin of the tarsus to adhere to this border so that it will not curl up and roll over the lid margin. In like manner, cauterization of the conjunctival side in hypertrophic ectropion probably causes the conjunctiva to attach itself to the inner border of the tarsal plate. Sometimes in advanced age there will be considerable tearing with a patent drainage canal, often due to lax skin plus a hypertrophy of the conjunctiva. Making only a few punctures immediately inside the canaliculus will bring in the lid margin just enough so that the lower punctum will contact the globe and again siphon off the tears.

It is well to contemplate the width of the tarsal plate in selecting the type of operation for correction of contractile entropion. The tarsus of the lower lid is much narrower than that of the upper; the width of the normal upper being about 10 millimeters and that of the lower about 5 millimeters. Hence in surgical correction of the upper lid, where the tarsus is still wide we may attach the cut edge of the skin near the lid margin to the top of the cleaned tarsus and have a right to expect a satisfactory result. This may be further improved by removing the thickened orbicularis attached to the tarsal plate, producing a wider palpebral fissure. The lower tarsal plate is seldom wide enough to justify utilizing this method so the modified Green Ewing method is recommended, as this does not require a wide tarsus.

The eyebrow is thick and curved so as to protect the eye from sweat and blows. It also helps shade the eye from excessive light by bending over. It should not be plucked and if destroyed by injury should be restored for this and cosmetic reasons. The lashes serve the same purpose and need not be trimmed before surgery. It is often a great advantage to grasp the lashes after operation to pull the lid away from the eye in closing it. The lashes can be replaced by a narrow graft from the

tablished osteomyelitis following a compound fracture is a problem in the care of the local area supported by systemic treatment to aid in combating the infection and supporting the patient constitutionally. Open drainage with removal of infected areas by saucerization permits drainage after the infection has become localized. This is a principle similar to the treatment of localized infection of other parts. A lesson which has been learned from World War II is that large open defects must not be allowed to remain to depress the vitality of the patient. Skin grafts should be applied as soon as clean granulations have covered the drained area to minimize loss of fluid and discomfort to the patient. These should be applied early even though they are not sufficient in themselves to give good permanent coverage to the area. When such wounds have been properly covered the patient is more comfortable and early reconstructive surgery can be accomplished with the aid of antibiotics.

Prior to World War II it was considered poor surgical judgment to attempt reconstructive surgery in the area where infection had taken place because of the possibility of reactivating the infection. On one of the large orthopedic services (2) of a general hospital in the Zone of the Interior 90 per cent of the procedures were done through the original incisions with approximately 5 per cent flare up of infections. Bone grafting to fill defects was also performed 6 to 8 weeks after wound healing. This has been made possible by general supportive measures and the use of sulfonamides and penicillin systemically. The value of appropriate chemotherapy before and after operation in the care of osteomyelitis cannot be stressed too strongly and prolonged administration is of definite value (5).

Reconstructive surgery of the skeletal system should not be done in the presence of draining sinuses, open draining wounds, or any clinical evidence of wound infection. This concept is no different than it was before the

war. Penicillin or sulfonamides cannot be expected to be of value in the presence of undrained abscesses, the presence of sequestra, detached fragments of bone with aseptic necrosis or any other foreign body.

Frequently large open wounds with considerable loss of skin, muscles, tendons, nerves, or blood vessels with bone trauma may be diagnosed as osteomyelitis incorrectly because of the constant drainage or "weeping" from granulation tissue (4). In such cases the drainage will usually stop when the wound is closed by a skin graft if osteomyelitis is not present.

The differences in the care of compound fractures in World War II as compared with World War I are striking. In compound gunshot wounds during the first year of World War I the total mortality was reported to be about 60 per cent (6). With emergency splinting on the battlefield the mortality was reported to be about 12 per cent at the end of the third year. During and following World War I compound fracture wounds were debrided and packed open with vaseline gauze with immobilization by plaster. This continued as the accepted form of treatment even during the late Spanish Civil War (7).

The present concept in the treatment of compound fractures which has resulted from World War II has decreased the morbidity and the incidence of chronic osteomyelitis. The application of the principles usually accepted for other infected wounds, as well as the use of chemotherapy has improved the results in cases of chronic osteomyelitis.

APPLIED ANATOMY IN EYE SURGERY

MEYER WIENER, M.D. F.A.C.S. Coronado California

APPPLIED anatomy serves a twofold purpose. It gives a precise basis to those occurrences and procedures that especially involve anatomical knowledge, and, in addition, it converts an otherwise unusually dull subject into one of interest by associating it with something manifestly useful and practical.

The student of anatomy has a somewhat hazy fanciful notion that his study of anatomical structure will, in some way and at some future time prove useful to him. By incorporating with it its surgical application he is made aware of its value in very much the same way as a series of experiments in laboratory physics relates to sheer theoretical, scientific data.

While it is assumed that eye surgeons, in general are acquainted with most of the premises which I am presenting it is with the hope that the memory of the dissecting days which have been growing a bit gray with some of us will wish to recall some of the anatomical matters which have the most direct bearing on surgical practice.

In surgery of the lids we must constantly bear in mind the delicate nature of the skin as well as the changes which come with advancing years which have a direct connection with surgical performance. The skin of the eyelid is the most delicate in the body pale and loosely attached. The foreskin approaches it most nearly in texture. However, it is not wise to use foreskin for lid replacement because, for some unknown reason, it nearly always becomes deeply pigmented. If not much is needed, the skin of the opposite lid is ideal if available. Probably next in order is that just back of the ear, or that from the inside of the arm.

In old age the skin atrophies and loses its elasticity due to atrophy of the elastic fibers. This sometimes induces spastic entropion since the overaction of the orbicularis has no

resilient skin to overcome it. The Ziegler cautery is effective by causing the skin corresponding to the lower margin of the tarsus to adhere to this border so that it will not curl up and roll over the lid margin. In like manner, cauterization of the conjunctival side in hypertrophic ectropion probably causes the conjunctiva to attach itself to the inner border of the tarsal plate. Sometimes in advanced age there will be considerable tearing with a patent drainage canal, often due to lax skin plus a hypertrophy of the conjunctiva. Making only a few punctures immediately inside the canaliculus will bring in the lid margin just enough so that the lower punctum will contact the globe and again siphon off the tears.

It is well to contemplate the width of the tarsal plate in selecting the type of operation for correction of contractile entropion. The tarsus of the lower lid is much narrower than that of the upper, the width of the normal upper being about 10 millimeters and that of the lower about 5 millimeters. Hence in surgical correction of the upper lid, where the tarsus is still wide, we may attach the cut edge of the skin near the lid margin to the top of the cleaned tarsus and have a right to expect a satisfactory result. This may be further improved by removing the thickened orbicularis attached to the tarsal plate, producing a wider palpebral fissure. The lower tarsal plate is seldom wide enough to justify utilizing this method so the modified Green Ewing method is recommended, as this does not require a wide tarsus.

The eyebrow is thick and curved so as to protect the eye from sweat and blows. It also helps shade the eye from excessive light by bending over. It should not be plucked and if destroyed by injury should be restored for this and cosmetic reasons. The lashes serve the same purpose and need not be trimmed before surgery. It is often a great advantage to grasp the lashes after operation to pull the lid away from the eye in closing it. The lashes can be replaced by a narrow graft from the

brow or from the hair line back of the ear. Recently Goldzieher reported some preliminary experiments he made on the skin of three elderly women after some previous experiments on dogs. He applied two estrogenic substances, estradiol and stilbestrol daily to the inner areas of the arms and thighs for a period of 6 weeks. Small sections of the skin taken from these areas showed restoration of the width of the epidermis, the number of cell layers increased, the individual cells larger and the elastic fibers more numerous.

I have seen the skin of the upper lid so lax that it drooped down and cut off some of the temporal field. For this reason as well as for appearance sake, a strip of it was removed.

The levator palpebrae is inserted in the skin of the upper lid, the lower third of the tarsus and along with Mueller's muscle to the upper edge of the tarsus. It is mainly these latter fibers with the attached aponeurosis that we use in Canan's operation, where the paralyzed levator is attached to the tendon of the superior rectus.

The lymph channels from the upper lid pass through the preauricular node, those of the lower lid, the submaxillary node (Treves). This is important in differentiating the lead of drainage in infections and sometimes helps in locating orbital infections where the septum orbitale has been penetrated.

Paralysis of the sixth nerve is particularly associated with fractures of the base of the skull, owing to its long course beneath the dura and its close confinement beneath the petrosphenoidal ligament. In fact, it was Pannas who first recognized that a fracture of the base of the skull might be manifested by a paralysis of the sixth nerve alone. Crepitus of the lids usually denotes fracture of the nasal bone, although fracture of any of the bones forming the nasal sinus cavities connected with the orbit may give rise to air in the orbit or lids.

The orbital cavity is about half an inch wider in the horizontal than in the vertical direction. Therefore it will be seen that there would be more space between the eye and the orbital wall on the sides than above or below and the greatest interval between the globe and the orbital wall is on the temporal side.

For this reason, growths which start on or at the apex of the orbit, or even on the opposite side, may soon find their way to the temporal side of the orbit. Dermoid cysts of the orbit are almost invariably found on the outer side, and although they may appear small, on operation will be found to extend to and be attached very close to the apex of the orbit. It is possible that the orbital septum keeps them within bounds and from protruding forward to any extent.

An intraorbital growth which is not within the intramuscular cone and presents on the temporal side can be reached better through a conjunctival incision than by one through the skin. Sometimes, even with the assistance of x rays, it is not possible to tell whether the growth is beneath or above the periorbits and exploration only will determine that fact. If the bone of the periorbita is involved then access through a skin incision is best. To reach growths in the intramuscular cone a Kroenlein approach seems best. In performing this operation, guard against severing the external rectus too far back or a paralysis may result. If the tendon is cut instead of the muscle belly it can be sewed together without fear of this happening. In performing evisceration of the orbital contents, it is done easily and quickly by separating the periorbita from its attachment to the wall of the orbit and then continuing to loosen it with a periosteal elevator back to the apex, then cutting off the entire mass from its apical attachment. A clean orbital wall is thus secured and with a minimal amount of bleeding. The cavity must be kept packed sufficiently tight to keep the lids on a stretch, which will otherwise shrivel and atrophy. Of course, if one does not expect to preserve the lids and eventually fill up the orbital cavity, then the lid margins may be freshened, sewed together and utilized to serve as a covering for the denuded orbital wall.

The conjunctiva is very loosely attached to the globe in man. The reverse of this is noted in operating on animals' eyes even in monkeys. Man having a smaller cornea in proportion to the size of the globe than any other animal, necessarily has more of his sclera covered with conjunctiva, exposed than any other creature. The negro, having a larger eye than

the caucasian, makes this still more noticeable. This makes it easier to perform surgery on man than on animals, as anyone who has experimented on animals' eyes will have observed. There are other reasons also. This looseness of the conjunctiva is of value in eye surgery in several ways, such as making conjunctival flaps to cover the cornea, correcting mild cases of symblepharon and in other plastic procedures. The distance of the conjunctival fornix from the upper lid margin is from 20 millimeters to 25 millimeters. The tarsal plate is from 10 millimeters to 12 millimeters wide. The distance of the fornix to the corneal margin is 8 millimeters to 10 millimeters. Hence, we have a loose surface of conjunctiva 18 millimeters to 22 millimeters wide from which we may easily take half or three quarters for use of a conjunctival transplant on the other eye socket, or for use in restoring the lining of the canaliculus in a plastic operation for restoring its lumen.

Pterygium is described as a conjunctival growth extending over the cornea. At any rate, the underlying cornea is always involved with destruction of Bowman's membrane not only immediately beneath the pterygium but according to Fuchs, to a point about 3 millimeters beyond the apparent apex. In my experience recurrences can be almost invariably prevented if one includes this involved corneal area in his dissection and resects a few layers of the cornea proper beneath the destroyed Bowman's in dissecting off the pterygium.

The most common tumor of the conjunctiva is the naevus. Many are not pigmented and few of them are malignant. About 10 per cent of the tumors are dermoids and in their removal one must bear in mind that the underlying sclera may be very thin.

While ballooning out the retrotarsal fold with 2 per cent procaine to which a drop or two of epinephrine has been added will completely anesthetize both surfaces of the lids for practically all operations on the lids proper so that no pain will be experienced when the tear drainage apparatus is involved, more than that is required. For the lids all of the terminal nerve endings are thus caught supplying the entire thickness of the lids. In order to anesthetize the canaliculus and sac so

that no pain will be felt by the patient to catch all of the nerves supplying the canaliculus one must first instill a drop of pontocaine then insert a small wad of cotton soaked with pontocaine and epinephrine in the inner canthus and after waiting about a minute insert a fine hypodermic needle into the conjunctiva just behind the punctum and slightly temporarily to it, inject a drop or two of the solution of 2 per cent procaine. The needle is then advanced in the loose tissue along the course of the canaliculus and drop by drop injected additionally as it is pushed toward the sac. When it reaches the periosteum covering the sac wall a sharp momentary pain is felt until a drop is injected here. Here, the periosteum is very sensitive as the main branches of the supratrochlear and infratrochlear nerves are encountered. One may now pass the dilator and probe into the canaliculus and down through the sac without the patient experiencing any pain. This, together with the anesthetization of the nasal mucosa by the otolaryngologist is sufficient for the intranasal dextrocytorrhinostomy.

In doing an extranasal operation or in removal of the sac, one must block the supratrochlear and infratrochlear and the infraorbital. In passing a probe down the nasal duct one is much more apt to make a false passage with a small probe than with a large one. The lumen of the sac is not just a smooth tube, but is often sacculated in such a manner that the small probe will pass into one of these pockets and penetrate the lining whereas a larger one might spread the lumen so as to obliterate the defect temporarily and go right on through. Pictures of these anatomical variations illustrated in both Whitnall and Schaeffer should impress this fact on our minds with impelling force.

One of the most frequent sources of failure in performing any type of intranasal tear sac operation is the failure of the surgeon to make his opening through the bone and sac inside the nose low enough so that the fluid will drain into the nose and not leave a pocket below the opening holding pus. Another of course, is failure to keep the opening patent. It is essential that the puncta be in contact with the globe and that the canalicula not be slit, in

order to have complete drainage. The canaliculae are also shortened by blinking making them wider and thus helping to carry off the tears. In old age when laxity of the skin sometimes causes the puncta to drop away from the globe, relief can be had by a limited Ziegler cauterization.

In operations on the cornea it is well to recall that normally it is thinnest at the center where it averages about 0.8 millimeter widening at the periphery to about 1.2 millimeters. It gets thinner with advancing years and may be less than 0.5 millimeter at the center in the aged. This, plus the loss of resiliency accounts for the sinking in or collapse of the cornea in very old people after cataract incision. A bubble of air injected into the chamber will maintain the normal curvature of the cornea until it has healed.

While Bowman's membrane, if destroyed never regenerates, it is not an essential part of the cornea for either visual or protective purposes. One may resect a corneal scar and obtain clear vision in its absence with apparently no more hazard to infection in its absence than if it were present. In resecting the cornea for corneal scar or peeling it off it is well to bear in mind several things. First, the formation of connective tissue producing the scar creates a much thicker protective shell than the normal cornea. This means that the cut, in preparation for peeling, must be deeper than one would make in a normal cornea, in order to get below the scar formation. Most eye surgeons fail in their corneal resections by not keeping this fact in mind. It also requires more pressure with the knife. It is also less flexible than the normal cornea and cannot be pulled back too much without endangering perforation of the thin underlying transparent cornea. Second in making the crucial incision with the scalpel don't forget that you are not cutting on a flat surface, but over a convexity with a radius of about 80 millimeters. Hence, the handle of the knife must be raised in starting the incision at the limbus and gradually lowered as the cut proceeds toward the opposite margin so as to keep the cutting edge, and not the point of the knife, in contact with and conforming with the corneal curve. This enables one to make his primary

cut much deeper without the danger of perforation. Third, and no less important an anatomical point to bear in mind is that the lamellae, normally about 60 in number and from 1.3 microns to 2.5 microns thick, run the entire width of the cornea, crisscrossing with each other at right angles and with very little interlacing so that they run almost parallel to the curved surface. When one picks up a single section to be peeled off it is essential that he stay in the same layer as that in which he started otherwise whenever he cuts across the intervening layers, connective tissue will form with resulting scar. By following proper technique, closely watching the line of cleavage, this is not difficult to do.

In an article by Edward Jackson on "The Function and Structure of the Eye," he stressed the fact that transparency depends on permeability to some substances of the transparent membranes, which included Bowman's and Descemet's in the cornea, capsule of the lens, Bruch's membrane of the choroid, and their impermeability to others. Rupture brings about loss of transparency. The cornea may lose its transparency from transudate or edema, as in glaucoma exudate, as in keratitis blood staining from blood in anterior chamber becoming hemolyzed scar tissue formation and dissolving of the cement substances between the lamellae in the stroma so that the refraction index is interfered with. This latter is probably due to infiltration of aqueous, such as that due to rupture of Descemet's from birth injury. Edema due to entrance of fluid through the epithelium can be differentiated and temporarily cleared by the glycerine test suggested by Cogan. Jackson lays continuous stress on the resilience of the cornea and refers to Salzmann's description of the arrangement of the layers, because it is more important and easier to understand when considered as a provision for resilience. Hence, no compression bandage after a corneal cut or cataract operation and keeping the wound elevated. He quotes Ellett, speaking of sutures in cataract operation "I think it does give a relative assurance against prolapse, but then there is still enough trouble from this source to lead me, after a rather extensive trial of the simple operation to give up

in favor of the combined operation, except in such cases where the cosmetic effect was a thing to be considered.' Jackson used no corneal suture relying upon the resiliency of the cornea.

The elasticity of the cornea is greater in the vertical than in the horizontal direction which may account for the astigmatism in glaucoma according to Schreder who found it to be anisotropic that is exhibits different properties when tested in different directions.

The cornea is about 12 millimeters in diameter, but the sclera extends 1 millimeter over the edge in the horizontal and 2 millimeters in the vertical meridian. In some cases it extends 3 millimeters or even 4 millimeters over the edge in the vertical meridian especially so in glaucoma cases. This is a fortunate arrangement in relieving the cornea. This broad limbus is marked in bydopthalmus too.

The epithelium around the limbus is potentially a pigment bearing tissue this can especially be noted in animals one may therefore get a pigmented papilloma at the limbus with out its being a melanoma.

The sclerocorneal junction is the weakest part of the eyeball. Rupture of the globe at this point may find the lens under the conjunctiva. If the lamina papyracea, which forms the inner wall of the orbit, should rupture then the eyeball will not rupture. One or the other may rupture, but never both. Decemet's membrane may rupture in birth injuries or in keratoconus and lead to permanent clouding of the cornea, probably through absorption of the interlining cement substance of the layers. Decemet's membrane is easily detached, as happens in doing a trephine or cyclodialysis. It curls under certain conditions and is very elastic. Unlike Bowman's it rapidly regenerates. It is really a crust formation laid down by the endothelium lining the inside of the cornea. This is contrary to the opinion of Elliott, who stated that it and the endothelial lining never regenerated and recommended denuding the endothelium just beyond the limits of the trephine opening so that the opening would not fill up.

At the periphery of Decemet's membrane in most people lies the anterior marginal ring as a circular band. It may go only part way

around and be rudimentary and can be seen with the gonioscope. Decemet's membrane is more resistant, both to the trephine and to infection than is the stroma. One may find 'warts (cornea guttata) around the periphery of Decemet's, which can be seen with the slit lamp and sometimes with the gonioscope. So long as they remain in the periphery they are of no special significance but if located in the center of the cornea the vision may be reduced as much as down to 20/40 or 20/70, and this must be kept in mind in cases of otherwise unexplainable reduced vision. They sometimes permit the aqueous to leak into the cornea.

There are a number of things which make knowledge of the scleral structure a matter for serious consideration in eye surgery. The sclera is about 0.6 millimeter thick at the limbus. Just back of the insertion of the muscles it is thinnest — 0.3 millimeter or less. This is where the sutures for recession are placed, and fortunately need not, and should not be deep. Going back to the equator it thickens to 0.6 millimeter and increases to 1.0 millimeter in the back. At the point of entrance of the optic nerve it is very thin owing to the perforations of the lamina cribrosa. On account of this inequality of the thickness one can easily see the futility of using pins in operating for retinal detachment for, if the pins are set for the proper depth in the thin area, they will not be deep enough where the sclera is thickest. The reverse is also true. The zone overlying the ciliary body is a circular area concentric to the limbus 5 to 6 millimeters back. The equator is 13 to 14 millimeters back of the limbus. The area of the venae vorticosae is represented by a concentric band 3 millimeters wide and 18 to 21 millimeters back of the limbus, or 5 to 8 millimeters back of the equator. The superior temporal vena vorticiosa lies 7 millimeters back of the equator, the superior nasal 7 to 8 millimeters the inferior temporal 5 millimeters and the inferior nasal 6 millimeters. These exits can be seen and in operations for detached retina and posterior sclerotomy these positions must be kept in mind. In posterior sclerotomy it is best to keep near the equator to avoid these and the long ciliary vessels.

Calcification of the sclera is very common in old age and follows absorption of the elastic

fibers in the sclera. This tends to give one the impression of increased intraocular tension by the finger test which is not borne out with the tonometric measurements. Again the point of the cataract knife may encounter one of these hard particles and interfere with making a satisfactory section. They are usually found on the nasal side as grayish depressions, about 4 millimeters back but exceptionally may appear further forward near the margin. If this process is far advanced the eye loses its power to adjust itself to lessened volume, as when the chamber is opened and the lens removed this can be made up by injecting air into the chamber. This factor may account for choroidal detachment, according to Fuchs.

The emissary perforations in the sclera lie 4 to 6 millimeters back of the limbus and are of great importance. Sometimes the long ciliary nerves loop up and look like small, gray tumors in this region. These have been excised under this delusion which is followed by anesthesia of the corresponding width of the cornea. They can be easily differentiated after having first anesthetized the eye by grasping the mass which induces severe pain. Old glaucoma can often be suspected by the enlargement of the ciliary arteries emerging suddenly from these openings, giving the impression of being more greatly enlarged than they really are. New growths of the ciliary body often emerge from the emissaries and give the impression that they are autonomous, localized ones. Transillumination and other means will determine such.

The sclera is loosely attached to the choroid except where the vessels and nerves penetrate it. In making an incision for cyclodialysis, a sharp corneal hook picks up the sclera, making it very easy to cut through the sclera without touching the choroid, since traction with the hook pulls the sclera away from the choroid. Be sure to make the cut in a place free from vessels which is not hard.

In performing posterior sclerotomy for glaucoma, it is essential to use a knife just as sharp as one would wish for in making a cataract incision and thrust it quickly through into the vitreous with the blade parallel to the antero-posterior fibers so as not to separate the retina from the choroid. As the blade is withdrawn

the incision is enlarged toward the posterior pole. There is a definite place for this little used operation one of which is in cases in which after a drainage operation the iris or ciliary body has come forward into the wound following an apparently successful operation, causing the tension to rise again. The release of the pressure behind the lens will often cause the ciliary hernia to recede and remain back. There need be little or no bleeding if the technique is carried out properly. This admonition must also be heeded in making the incision for the removal of foreign bodies by the posterior route. In this case the incision must be fully 50 per cent larger than the largest diameter of the foreign body for one never knows which end is coming first and it may even come broadside. A long incision heals just as quickly as a small one and does not invite danger of retinal detachment, in my experience, even though one fails to perform electrocoagulation as a preventative measure.

The capsule of Tenon is both membranous and elastic. It is more or less adherent at the attachment of the muscle tendons and in some places to the fat of the orbit. Semeraro found that in tests carried out on the cadaver Tenon's capsule is nonexistent in some cases. This fact may account for the slipping out of the capsule of the implant in many cases of enucleation where the operation seemed to have been well carried out. We have never encountered this condition in the living eye in the many operations involving the muscles, although it does seem to be much less developed in some cases than in others. There is no actual space between the ocular surface of the capsule and the orbital surface opposing it, but the two are connected by a felting of very fine strands of connective tissue. These are loose enough to permit the eyeball to move freely in a limited way but in extreme excursions both globe and capsule move together as a whole in a bed of orbital fat, which is loosely connected to the capsule behind. There is a difference of opinion as to how far forward the capsule extends. Sobotta states that it terminates at the upper retrotarsal fold and at the insertion of the muscles. Most authorities agree that it blends with the conjunctiva as far forward as the corneal margin.

Where the vessel sheaths blend with the capsule, they give offshoots to the orbital walls known as the check ligaments. We shall speak of these in a moment. The septum orbitale is a thin membrane of connective tissue which extends from the entire orbital margin toward the palpebral opening and tends to hold infections to either the orbit or to the anterior part of the globe. The capsule of Tenon as well as the periorbita and the sheath of the optic nerve, are continuous with the dura. For this reason it is dangerous to perform enucleation in panophthalmitis with marked cellulitis of the orbit, as it may lead to meningitis and subsequent death of the patient. I saw this happen once while I was a medical student. Evisceration is here indicated. In removing the contents of the globe it is imperative that no remnant of the uveal tract remain. The choroid is firmly attached in two places posteriorly, where the posterior ciliary vessels and nerves enter and in front where the anterior vessels and nerves pass through the emissaries. These points must be most carefully inspected on conclusion of the operation. When all of the pigmented material has been removed, the sclera will be seen as a white smooth surface and there will be no bleeding. If the usual enucleation is done and a glass ball is inserted it is well to figure out just how large the cavity is so that too large a one will not be introduced and be expelled. If we could count on preserving every bit of capsule as far forward as the attachment of the muscle tendons and not allow any for the depth of the sutures, then we might easily put in a 14 millimeter or even a 15 millimeter implant in the capsule. However, anteriorly the capsule is so intimately connected with the sclera that it isn't detached for several millimeters back of the insertion. Therefore, if one inserts a small ball, not over 12 millimeters in diameter there will be less stretching of the capsule in sewing it in and more likelihood of it not being expelled. This rule holds good, also for implanting after evisceration for the reason that taking off all of the cornea and part of the sclera lessens the diameter of what remains. It would seem that Burch's recommendation of leaving the cornea intact and implanting a larger sphere should give a far better result.

In a clean enucleation it is not necessary to sew the tendons together for they are closely attached to the capsule and fall naturally together whether the capsule be sewed or not. In enucleating a globe for absolute glaucoma where we have a very deep cup, if the nerve is cut too closely one is apt to lose vitreous for there is no vitreous hyaloid membrane either over the nerve head or the ora serrata. Women's eyes are larger than men's and the negro eye is larger than that of the white man hence, a slightly larger implant can be used.

In man, the conjunctiva is very loosely attached to the globe except at the limbus. It stretches readily. The capsule of Tenon is supposed to run forward beyond the attachment of the muscle tendons to blend with the conjunctiva. For all practical purposes one can almost forget it is there, unless it constitutes the deep layer under the loose, conjunctival connective tissue which hugs the sclera. In making a flap for sclerocorneal trephine, one must hug the scleral surface closely with the blunt scissors in order to obtain a thick, protective flap. At the point where the sclera and cornea join, the knife is substituted and the cornea split. One can easily determine when the cornea has been reached by its bluish appearance. The same technique for splitting the cornea in a sclerocorneal trephine is recommended as in the resection for corneal scar. If properly done it requires less than a minute's time.

In exposing the muscle tendons for advancement recession or enucleation the capsule of Tenon should be disturbed as little as possible and none of it lost. Make the incision in the conjunctiva large enough for freedom of operation for a large incision heals just as easily and quickly as a small one. When the area to be explored is sufficiently exposed remember that immediately under the conjunctiva and over the capsule is some loose connective tissue which will be grasped by the forceps in stead of the capsule if it is not pushed aside. To accomplish this place the flat fixation forceps so that the blades will be closed and parallel to the length of the tendon press it down on the globe and at the same time, separating the blades while still maintaining the pressure. It is necessary that the forceps have

a strong spring in order to do this properly. Then, without releasing the pressure, separate the blades about 2 or 3 millimeters and then make increased pressure against the sclera so as to indent it while closing the blades. The forceps will now have a good hold on Tenon's. Keep the grasp firmly make a snip with the scissors close to the end of the forceps while pulling it slightly away from the sclera keep the original grasp on the capsule until the hook has been slid under the tendon. The reason the blades must be kept parallel to the length of the tendon is that when the eye is rotated to expose the area, the capsule, as well as the tendon is put on a stretch which makes it easy to be grasped thus and very difficult if it is attempted against the stretched tissue.

The average distance for the attachment of the recti muscle tendons back of the limbus is, medial 5.5 millimeters inferior 6.5 millimeters lateral 6.9 millimeters superior 7.7 millimeters. Hence, the forceps must be placed far enough back to catch the free side of the tendon. Of course, these measurements vary considerably and, according to Motals they may be as far back as 7 millimeters for the medial and 11 millimeters for the superior. It is better to allow for the maximum than to get too far forward. It is also well to bear in mind the width of these tendons so that in first placing our forceps in position we will not include any of the tendon fibers. The average breadth of the tendon varies from 9.2 millimeters for the lateral to 10.75 millimeters for the superior. Thus one sees that in placing the forceps it is well to be about 6 to 7 millimeters beyond the estimated center of the tendon to be exposed. While the medial rectus is thickest and strongest, its tendon is also the shortest, averaging less than 4 millimeters in length while the lateral, which is the weakest, is nearly 9 millimeters long. It also must be noted that the lines of insertion of the tendons are not straight, but are curved, or even wavy and do not lie parallel to the corneal margin. For example, it is easier to approach the tendon of the superior rectus from the medial side than from the temporal since it is several millimeters closer to the limbus nasally.

The superior oblique attachment to the globe lies just behind that of the superior rec-

tus. Therefore, all one has to do to expose the superior oblique tendon is to engage the attachment of the superior rectus tendon with the hook, reverse the pull by turning the hook and draw the hook backward, thus engaging the tendon of the superior oblique and pulling it forward into the conjunctival wound.

Since the inferior oblique arises from a small depression on the orbital floor just within the inferior orbital margin lateral and close to the nasolachrymal canal, it can be easily exposed by a deep incision into the lower conjunctival sulcus deep enough to strike the perosteum on the floor of the orbit, introduce the hook into the opening until it strikes the floor and then sweeping it nasally until the resistance of the attachment is felt whereupon it is drawn into the wound.

Stitches for a recession are placed where the sclera is thinnest. Fortunately the stitches in this case need not be and should not be as deep as for advancement, for there is less pull on the muscle operated upon after than before the operation for two reasons. First, because the tendon is set farther back, and because the muscle is partly paralyzed from handling. If all of these rules are followed out, bearing in mind the anatomical features mentioned, the tendon of any of the muscles, either straight or oblique can be caught with the first sweep of the hook. Failure to do so means faulty technique.

The attachments of the capsule of Tenon to the margins of the orbit prevent the muscles from entirely retracting and, even when the globe has been removed give them bases to act upon, thus preserving some motility in the stump. Rough handling of these attachments so as to mutilate these parts of the capsule can result in an ugly proptosis after a strabismus operation or sinking of the globe after enucleation. When a part of the capsule known as the suspensory ligament of Lockwood is mangled the eyeball drops or there may be excessive lateral rotation of the globe or upward movement. Instruments should always be sharp so that clean cuts can be made with the scissors instead of tears. Clean cuts heal easier and are less prone to infection.

O Connor suggested a novel method of increasing the effect of the Himmelsheimer oper-

ation by utilizing the nasal third of the rectus muscles, turning them under the rectus tendons before sewing them laterally. The objection to this, however, is that it puts even a greater stretch on these transposed portions. A more secure method is suggested for this valuable conception utilizing the paralyzed, split rectus to attach to the vertical recti and then severing the nasal third of their attachment to the globe. This involves the same principle as the O'Connor method is easier to execute and eliminates the danger of tearing loose of the vertical strips.

In operating on the muscles in order to obtain complete anesthesia, it is necessary not only to instill an anesthetic in the conjunctival sac and inject the intramuscular cone but also to use a very fine needle and inject a drop or two into the muscle belly itself. While most of the sensory nerve endings terminate near the tendinous attachment, the tendon tissue is too dense for it to spread and complete absence of pain will be accomplished only by injecting into the muscle itself.

In a recent article on "Guides to Choice of Operation for Squint" Sugar stressed Biel's guide to choice of operation based on anatomical and physiological principles. They are important enough to repeat here.

1 When a difference in the two eyes under cover can be determined, the eye showing the smaller deviation is the paralyzed one.

2 When the vertical deviation of the paralyzed eye is greater in adduction an oblique muscle is involved (because the obliques help in adduction) and for the same reason when it is greater in abduction a vertical muscle is involved.

3 The image of the paralyzed eye is always seen in the direction in which the affected muscle should move the eye.

4 When tilting of images is marked and tipping of the head greatly increases diplopia, an oblique muscle is nearly always involved.

5 The principal action of a muscle should always be considered.

Klein in investigations concerning the lens capsule and its importance in the technique of intracapsular cataract extraction emphasizes the fact that the zonular lamella is a very thin membrane that covers the peripheral parts of

the anterior lens capsule and is easily separated from it. The posterior capsule is thinner than the anterior lens capsule, the central area of each is thinnest, the maximum thickness being between the equator and the center. In old age the zonular fibers become fragile and the capsule thicker (there is an exception, that of the Morgagnian where both become thin). By a special method, he found that the capsule can resist a pressure of 150 to 200 millimeters of mercury. He recommended traction on the lens capsule and simultaneous pressure at the limbus with a hook to rupture the zonule then, repetition of the maneuver in a different direction. In intumescent and hypermature lenses, as well as in those cases where there has been a previous uveitis, the zonule is so weakened that it is ruptured with a minimum amount of pressure so that the lens can be extracted by the Smith method without touching the capsule. These are the only cases where the Smith method is recommended.

Since the lens capsule is thickest between the center and the periphery this is where it should be grasped with the Arruga or similar forceps in breaking the zonule. There is a tendency of many surgeons in order to make sure of securing a firm hold on the capsule, to take too wide a bite. When this is done it stretches the capsule to such an extent that it is more liable to break before the zonule ruptures. The zonular lamellae may extend back as far as the ora serrata and if pulled upon too much can detach the retina or pull a hole in it. This may occur in doing an intracapsular, or even in doing a needling if not done properly. The lamellae may not attach and there may actually be a thickened capsule around the edge of the lens which may desquamate into the anterior chamber and cause glaucoma.

The anterior hyaloid has tremendous stretching qualities and may come forward after the cataract incision and be mistaken for vitreous. If the speculum be immediately removed and traction made by pulling down on the upper lid, it usually retracts and one may proceed with the operation. Here is another advantage of having lashes with which to grasp the upper lid in order to pull it away from the globe. There may be an anomalous

union of the anterior hyaloid with the lens capsule which proves a detriment to extraction in the lens capsule for in this case the hyaloid is torn and vitreous exudes. This anomalous condition cannot be determined beforehand.

In the embryo there is a sinus running around the pupillary area and in adult eyes cysts sometimes form in this sinus area separating the pigment layer. They may manifest themselves by floating down in the pupillary area as a black mass when we may assume that it is a cyst. If however the black mass is seen at the base of the iris melanoma must be suspected.

Tags near the base of the iris show a reversal to the pectinate ligament in lower animals. Normally in the human there are only a few trabeculae in the angle. These may extend from a peripheral iris knob which at times is present in the human. If present in a glaucomatous eye the synechiae will run from it to the angle.

The vessels of the iris run parallel with the radiations. Hence cutting the iris in the direction of the fibers in an iridectomy causes less bleeding and, at the same time, enables one to make a deeper iridectomy. For this reason I fail to see how a peripheral iridectomy in acute glaucoma can be as effective as a complete one, as claimed by some.

Sugar stresses the importance of knowing the depth of the anterior chamber in glaucoma and describes a method for measuring it by means of the McNair Bettman portable slit lamp. The important thing is the angle. Of special significance is the condition of the angle, which can be determined by gonioscopy. Through this means Barkan has developed the operation of goniotomy for congenital glaucoma, which consists of removing occluded fetal meshwork from the angle promising much for this hitherto almost intractable disease. Anderson's analysis of 84 specimens,

finding the canal open in 75 per cent of the early specimens and no trace of it in children over 2½ years of age, none of which had been operated on strengthens Barkan's warning for early operation in these cases, since the distention of the eyeball tends to obliterate the canal. Barkan makes the distinction between goniotomy in the infant, which consists of removal of fetal remnants from the angle versus trabeculotomy in the adult, whose object is to incise the angle wall that is, the trabeculum itself. In the May issue of the *Archives of Ophthalmology* an article appeared by Hughes and Gartner in which they recommended the removal of the aqueous, substituting air thereby deepening the anterior chamber so that it is possible to perform goniotomy in cases with a shallow chamber as well as in those cases with a wide angle.

described by Krimsky. A prism is held in front of the fixing eye with the apex toward the nose in a convergent squint. This causes the eye to shift toward the nose to resume fixation and the squinting eye will make a corresponding shift away from the nose. Thus using the fixing eye as a handle, and varying the size of the prism the squinting eye can be moved back and forth until the corneal reflex is accurately centered. This is exactly what is done with a Priestly Smith tape but the prism reflex test is considerably simpler to use. It can be used only for monocular squints. The perimeter is still the best method for obtaining distance measurements on a patient with poor fixation in one eye.

As soon as the child is old enough to cooperate (3 to 5 years of age) and if both eyes are capable of fixation the cover test of Duane is the method of choice for measuring squint. This method has been admirably set forth in the writing of the late James W. White. It will do all that he has claimed for it and we should all learn to rely on it very largely in the measurement of squint.

TREATMENT

Regarding the actual treatment of strabismus, it hardly seems necessary to urge that these children be seen as early as possible after 6 months of age. Unfortunately some pediatricians still advise waiting to see if a deviation will be outgrown but I believe that their number is diminishing. Possibly not much will be done in the way of treatment until the child is a year old but it is worth while to see him earlier to watch developments. Occasionally operation will be indicated as will be discussed later. Whatever therapeutic measures may be required it is undeniable that the earlier they are employed the more complications, such as amblyopia, abnormal retinal correspondence and muscle changes will be avoided or minimized and the chances will be better for binocular vision and fusion.

I believe that there is general agreement as to the value of giving glasses that fully correct any significant hyperopia or astigmatism. The accommodative squints do not often appear before a year, but the glasses should be worn as early as possible.

Amblyopia. In this air minded age good visual acuity in both eyes has become even more essential. This means that the correction of amblyopia ex anopsia is the responsibility of the ophthalmologist. Such correction can be accomplished in the majority of patients under 8 if time is taken to impress parents with its importance. Again the earlier occlusion is begun the more quickly will the result be obtained. As mentioned above, it is not necessary to wait until the vision can be measured to know that you are dealing with amblyopia. If the squint is solidly monocular you can assume that the squinting eye is amblyopic and proceed with occlusion. By watching the behavior of the eyes when the occluding bandage is changed, one can proceed with confidence and safety. As long as the originally fixing eye resumes fixation whenever the bandage is removed, the objective has not been achieved. In young children, it is easy to cause fixation to shift to the previously squinting eye, an event that distresses the mother but pleases the doctor because it proves that both eyes are sound. There is no way to differentiate amblyopia ex anopsia from a true amblyopia. In little children so all patients should have a trial course of total occlusion for at least 2 months. At the beginning of occlusion anything short of total occlusion 24 hours a day is apt to be a waste of time. It is easier for the child to have it on all the time it will bring the result most rapidly. A firm adhesive bandage over cotton, is the occluder of choice. Later and this will vary from 2 to 8 weeks or more, various occluders can be used on the glasses, but I rely largely on atropine in the better eye with paper on that spectacle lens. It should be apparent that atropine alone will be successful only in cases of slight amblyopia or extreme hyperopia when combined with an occluder on the spectacles, the drug will only succeed after the squinting eye has acquired the ability to fix.

ORTHOPTIC EXERCISES

It is extremely difficult if not impossible to get an idea of the true value of orthoptic exercises from the literature. There is no way to reconcile the highly optimistic report of results obtained by Berens and his associates

with the completely negative report of Fowler, both are competent reporters but they cannot possibly both be right. Unfortunately in the majority of articles reporting indications for orthoptic exercises and the results of orthoptic treatment, definitions and classifications of cases are either absent or so indefinite that few conclusions can be drawn. There is yet no unanimity about the value of orthoptics. In the opinions of many ophthalmologists, it has failed to achieve an established position in the treatment of squint. Yet it is being used by far too many reliable clinicians to be ignored.

It has not been my practice to use orthoptic exercises routinely in healing strabismus. This decision was reached after experience gained while in charge of an orthoptic Clinic at Vanderhilt Clinic, in New York, from 1935 to 1938 while serving on the American Orthoptic Council for several years and from reading the orthoptic literature closely. There are two principal reasons for my decision. First, it was not possible for me to predict the outcome of orthoptic training with sufficient accuracy to feel justified in prescribing it for my patients. No doubt there are orthoptic technicians who can make fair prognostications of their own management of these cases. However if an ophthalmologist is going to use this method of treatment, he too must be able to tell his patient approximately what he has a right to expect in a given time. At the present time I am unable to do this.

My second reason is that I do not have the facilities for carrying out the treatment. Most of us do not have a sufficient number of muscle cases to employ a full time technician. The obvious solution is for several ophthalmologists to pool their cases and resources and set up a technician in a separate office. This has been done in a few cities with notable success but, at present, I know of only one technician in New York to whom private patients can be sent. As you may surmise, she is far too busy to do more than see an occasional case for any one doctor.

In spite of other practical obstacles there is no doubt that there is value in orthoptic exercises, that some patients with accommodative squint would get rid of their glasses more quickly and more certainly with training than

some patients with small deviations could avoid operation and more patients could achieve binocular single vision with fusion after operation. We need to learn a great deal more so that we will know which cases offer reasonable prospects of success and so that accurate prognoses can be given to our patients. In this direction, I hope to see many new orthoptic clinics established.

Age and indications for operation In recent years the trend in this country has been toward earlier operation until it is now not uncommon to do the operation while the child is in the neighborhood of 1 year of age. These early cases are of course those born with the squint, which means a true muscle anomaly. These are nearly all marked deviations with frequently a vertical complication. While refractive errors can hardly play a part at this age it is probably wise to do retinoscopic and fundus examinations, under ether if necessary. It is usually apparent that nothing but surgery will correct the deviation. The parents are distressed and embarrassed over the appearance of their baby. The avoidance of secondary muscle changes and the chances of re-establishing binocular vision, all greatly outweigh the disadvantage of operating without a complete analysis of the case. This analysis could be gained only after long delay.

In the larger group of cases that come on gradually after the second year and have more or less relation to accommodation operation should be delayed until other measures have been tried. Glasses should be worn for several months amblyopia corrected and possibly there should be orthoptic training. When these measures have been carried out, abandoned or considered unsuitable, operation is indicated regardless of the age. However, for psychological reasons great effort should be made to complete the essential preliminaries and to perform the operation before the child enters school. For the same reasons it may be desirable to shortcut the preliminaries in some cases and operate earlier. A serious objective to orthoptic training is that valuable time may have to be lost in waiting for the child to attain an age when exercises can be given.

Only in those cases with high hyperopic errors (usually +4 or more) where the deviation

is largely eliminated by glasses, should the operation be postponed indefinitely. The majority of these children will not require operation and at around 15 years they will be able to remove their glasses when not doing close work. When the occasional operation becomes necessary only that portion of the deviation remaining when glasses are worn should be corrected. Care must be taken not to weaken convergence unduly.

Choice of operation. It is almost impossible to tell someone else what procedure to do for a given deviation. Each surgeon must decide which of the many modern techniques makes the most sense to him and which he can do best. Exactly similar results can probably be obtained in several ways. Mention of a few general principles may be helpful. For the usual concomitant esotropia which measures a little greater for *near* than *distance*, a resection of the externus and a recession of the internus of the same eye are my choice. I operate on the squinting eye because it makes sense to the parents and the muscle changes will be in this eye. If there is a conspicuous overaction of the inferior oblique of that eye, a recession of this muscle at its insertion is done at the same time. Even if the overaction is bilateral, the inferior oblique of the fixing eye need not be touched as its overaction rarely becomes manifest. When the deviation is greater for *distance*, emphasis is placed on the resection of the externus when much greater for *near*, the recession of the internus is stressed, or possibly divided between the two eyes. In alternating esotropia, it seems logical to operate on both eyes and while this would probably give the best result, it is not practical to operate on 4 muscles when not absolutely necessary so I would handle them like the monocular squints. An exception to this is the very young alternator who uses the right eye to look to the left and the left to look to the right, and never abducts either eye. Here, bilateral recessions of the internus are indicated. In alternators there will frequently be bilateral overaction of both inferior obliques. If these are approximately of equal amounts and not extreme, they can usually be ignored.

The question of how much to do to correct a given deviation is constantly asked by the

Residents. The best suggestion that I can offer is the figure that Dunnington and I reached several years ago when we analyzed a fairly large series of our operations. We found that when we did a 10 millimeter resection of the externus and a 4 millimeter recession of the internus, on the same eye, we averaged 40 diopters of correction. This is only a rough guide but it provides a starting point.

While I do not want to stress technique because I believe that the many minute variations that have been described are unimportant, I do want to make an appeal to each surgeon to perfect his own technique. It is important that he be able to reproduce an operation with precision as that is the only way that he will be able to find out just what his operation will do. Eventually he will be able to translate accurate measurements into definite, predictable surgical results. I have been using the resection described by Lancaster for several years. Being able to tie the 2 mattress sutures while the tendon is still held firmly in the muscle clamp appeals to me as safer and more definite than other methods. For the recession of the internal rectus, I use two single arm sutures, one in the upper third of the tendon secured by passing the needle through the tendon a second time, and the other in the lower third of the tendon both placed as close to the insertion as possible. Great care is used at this point to waste as little of the tendon as possible. The sutures are then passed through the superficial fibers of the sclera, a measured distance from the stump and at least 8 millimeters apart so as to spread the tendon flat. The conjunctiva is closed with care 3 to 5 interrupted sutures being used. The recession of the inferior oblique is done by the method described by White (9). It seems to offer the best possibility for a graded weakening of this muscle. Avertin and ether anesthesia is routine. No cocaine plain catgut sutures or atraumatic needles are used throughout. I bandage only the eye operated upon and do not use atropine. The bandage is changed on the second operative day and removed entirely on the 4th or 5th. These details are mentioned only because they may be of interest, not because I believe that they are necessarily the best.

SUMMARY

Early examination by means of the symbol E to test vision, and measurement of the deviation by means of the corneal reflexes and the prism reflex test are emphatically recommended.

Treatment should start as early as possible and should include occlusion in all cases of monocular squint.

The reasons for not using orthoptic exercises routinely are stated.

Operation can be done safely at 1 year and in certain cases gives definite advantages when done early.

The indications for operation have been discussed and my choice of operations has been given briefly.

A NEW TYPE OF BASKET IMPLANT FOR USE AFTER ENUCLEATION

NORMAN L. CUTLER, M.D., Wilmington, Delaware

CONSIDERABLE thought has been given recently to the possibility of improving the cosmetic result in enucleation or evisceration procedures. It is probable that out of this interest will come improvements that will stand the test of time and use.

The ideal cosmetic result should achieve the following

1. Wide range of co-ordinate movement with the remaining eye.

2. Instantaneous movement over a short range.

3. Normal lid contour i.e. (a) no sagging of lower lid (b) no sinking in of upper lid.

4. Permanence of the implant. This implies that it shall not migrate or be extruded.

No procedure, whether enucleation or evisceration, with or without an implant has achieved all of these results up to this time. Different procedures have been devised as recently revealed by Dimitry that have resulted in a good movement of the stump but the problem has always remained of transmitting this movement to the prosthesis. The basket type implant to be described is a step toward improving the transmission of this movement from the stump to the prosthesis on what might be called conventional lines, i.e. the prosthesis is completely enclosed in tissue.

The purpose of a basket implant, with a resulting depressed area in the socket, is to give the prosthesis, which has a stud projecting posteriorly (Fig. 1) a grip on the stump. This necessitates, of course, a custom-designed prosthesis and, in addition, imposes new problems of design on the artificial eye maker. This is due to the fact that there is more ability of the cuplike depression to move the artificial eye than there is space in which the eye can move. Thus, it is necessary to adjust carefully the

size and shape of the prosthesis in order to use the minimum amount of space and still maintain a normal fissure. This is facilitated if no attempt is made to fill out a depressed upper lid with the prosthesis, but that is left to the surgeon.

The standard basket now used is shown in Figure 2A and B. It is made of lucite (methyl methacrylate) and measures 11 by 15 millimeters. This size seems to be the best whether the eye to be enucleated is large or small. The anterior edge is slightly thickened, the sides of the basket are fenestrated to allow for invasion of tissue. In addition, there are 3 holes in the bottom, measuring 1 millimeter in diameter 2 of which are for sutures. Larger and smaller baskets have been tried but a tendency to reduce movement has resulted in either case. Other materials are being tried, but lucite has been found satisfactory up to the present time. A lucite button, measuring 5 by 8 millimeters, with four 0.8 millimeter holes (Fig. 2C) is used to tie the sutures through and maintain the depression during healing. Three double-armed sutures are used: black No. 0 nylon, blue No. 00 dermal and purple coarse dermal. These are used because of their greater strength and smoothness, allowing sutures to be pulled up without breaking. They are of different colors to permit ready identification. One inch (2.5 cm.) straight intestinal needles are used to allow their passage through the plastic button.

At the end of the operation a special plastic retainer (Fig. 2D) is placed inside the lids after the method of Gifford. This greatly reduces postoperative edema, keeps the basket centered, and completely prevents any prolapse of the conjunctiva. The average operating time for this procedure is the same as for any implantation procedure, namely 22 to 25 minutes.

Two baskets slightly smaller than the standard have been placed inside the sclera after

Presented before the Clinical Congress of the American College of Surgeons, Cleveland, Ohio, December 6-20, 1946.

The illustrations in this article are reprinted through the courtesy of the *Archives of Ophthalmology*.

Fig. 1 Plastic prosthesis showing projecting stud on posterior surface.

visceration. No advantage accrued as far as movement of the stump was concerned and the depression into which the stud of the prosthesis fits was considerably smaller. In addition, there was extreme postoperative edema involving the entire side of the face which lasted 7 to 10 days. I have seen 2 cases in which a ball implant was placed in the sclera with extremely good movement practically as good as that of the normal eye but because of the smooth contour only a small amount could be transmitted to the prosthesis.

The muscles are not sutured in this procedure. Figure 3 shows the posterior view of a basket implant removed at autopsy 8½ months after operation from a patient who was killed in an automobile accident. It will

be seen that all the muscles including the obliques are attached near the rim of the basket.

OPERATIVE PROCEDURE

Anesthesia is induced by intravenous injection of sodium pentothal and retrobulbar injection of 2 cubic centimeters of 2 per cent procaine hydrochloride.

The eye is prepared in the usual manner. A speculum (Weeks) is inserted, the conjunctiva dissected from the limbus, and the dissection carried to the fornices in all directions. The rectus muscles are then isolated and cut free from their insertions. The conjunctival opening usually is enlarged nasally and temporally about 2 millimeters to permit passage of the globe. The globe is grasped with fixation

Fig. 2. A, Top view of lucite basket; B, side view; C, lucite stud; D, posterior view of lucite with central depression for stud.

Fig. 3. Posterior view of basket, implant removed at autopsy 8 months following implantation showing muscles attached to anterior edge.

forceps at the tendon of the internal rectus muscle and the nerve cut with enucleation scissors. The prolapsed globe is then freed from the oblique muscles and removed.

A dry gauze sponge and a little pressure usually reduce the bleeding quickly to enable one to inspect Tenon's capsule (Fig. 4).

The basket with one black nylon suture, size No. 0 fitted with two straight 1 inch

Fig. 5. Basket with No. 0 black nylon suture inserted; suture carried through Tenon's capsule and conjunctiva at 12 and 6 o'clock.

Fig. 4. Tenon's space exposed, ready for insertion of basket implant.

intestinal needles, is then placed in Tenon's capsule (Fig. 5). The upper suture is brought through a firm bite of Tenon's capsule at 12 o'clock and out through the margin of the conjunctiva. The lower suture is brought out similarly at 6 o'clock.

A blue No. 00 dermal double-armed suture with 1 inch intestinal needles is then carried through Tenon's capsule and the conjunctiva about 2 millimeters on either side of the black suture which was placed at 6 o'clock (Fig. 6A). Each suture is then carried through in a simi-

Fig. 6. A, Blue dermal mattress suture, carried through Tenon's capsule and conjunctiva on either side of black nylon from within outward and finally through Tenon's capsule and conjunctiva at 12 and 6 o'clock.

Fig. 7. Black nylon suture 1 carried through holes in lucite stud. B purple dermal suture, 3 carried through the same holes in stud as suture 1. Blue dermal suture, 2 carried through the other two holes in lucite button.

lar manner at 12 o'clock. The suture on the right side is now carried through Tenon's capsule and the conjunctiva at 3 o'clock on the same side and the suture on the left at 9 o'clock.

A purple dermal (coarse) double armed suture, similar to the blue dermal suture is now placed about 2 millimeters on either side

Fig. 9. A Suture 2 pulled up, imbricating Tenon's capsule and conjunctiva vertically. B Suture 2 tied and cut. Suture 3 pulled up tight and cut through, imbricating Tenon's capsule and conjunctiva horizontally and closing the basket opening.

Fig. 8. Button holder

of the blue suture at 3 o'clock, the needle taking similar bites of Tenon's capsule and coming out through the conjunctiva. These two sutures are now carried across above all other sutures and brought out 2 millimeters on either side of the blue suture at 9 o'clock (Fig. 6B).

These two mattress sutures (blue and purple) are placed as outlined in the preceding paragraphs so that when they are pulled up they cause a double imbrication or folding of Tenon's capsule and the conjunctiva and the black sutures still come out through the upper layer after this has been done. All sutures are carried through the lucite stud, as shown in Figure 7A and B. Sutures 1 and 3 pass through the same two holes and suture 2 through the other two holes.

While the assistant holds the button with the lower end at the level of the rim of the basket with the button holder (Fig. 8) the blue suture is pulled up, tied and cut (Fig. 9A) and then the purple suture is similarly

Fig. 10. Suture 1 pulled up, tied and cut forcing button with Tenon's capsule and conjunctiva down into the basket.

Fig. 1. Plastic retainer

handled. This pulls Tenon's capsule and the conjunctiva into place and closes the opening.

A single tie is now placed in the black suture and as this tie is gradually pulled up the index fingers make traction and a little pressure. The assistant then releases the button from the forceps. As this tie is pulled tight, it forces the button with Tenon's capsule and the conjunctiva down into the cup. Three knots are placed and the suture is cut (Fig. 10). No conjunctival sutures are necessary.

A lucite retainer is placed inside the lids. An adhesive dressing with firm pressure but with no roller bandage is applied.

POSTOPERATIVE COURSE

The first dressing is done on the third postoperative day, the retainer being removed and

the socket irrigated. The retainer is replaced and if there is still some edema an adhesive dressing is put back on for 2 more days. In most cases the dressing can be omitted. On the fifth postoperative day the sutures and the button are removed. A temporary retainer with button attached (Fig. 11) is placed in the socket at this time. This is removed daily and the socket is irrigated for a week.

In none of the cases in which operation was performed has there been any prolapse of the conjunctiva. This is probably due to the type of operation and to the retainer. In general, there has been little reaction and no discomfort at all after the first postoperative day.

At the end of 2 to 3 weeks, depending on the shrinkage of its tissues, the socket is ready for a custom made prosthesis, similar to the one shown in Figure 1.

COMPLICATIONS

It is important not to pull the sutures beyond the snug state, as otherwise pressure necrosis and exposure of the bottom of the basket will result. This complication will also occur if the button is not removed at the end of 5 days. If exposure of the bottom of the basket does occur a retainer without a button attached is put in, and granulation and epithelization will take place in a few days, without impairment of the result. If after the sutures and the button are removed on the fifth post

Fig. 12. Appearance of socket in patient's mouth after operation, showing impaction in the basket and the range of motion.

operative day there is a thin appearing lining on the bottom of the basket a plain retainer can be used from 1 to 3 days and then a button retainer employed

A sufficiently firm bite of Tenon's capsule must be obtained in placing the mattress sutures, since there is slight tension on the capsule when it is inverted into the basket. In 2 cases in which a ball implant was removed and a basket put in the sutures did not hold. This was also true in a case in which a considerable amount of scar tissue was present—the sutures cut through the inelastic scar tissue. It was necessary in these 3 cases to remove the baskets.

Postoperative hemorrhage has never been a problem in our cases. In the 3 cases just mentioned in which the sutures did not hold because of scar tissue and the basket was removed approximately 10 days after operation, it had to be dissected out. Certainly the basket cannot be extruded.

PROSTHESIS

The socket is ready for the final prosthesis at the end of 2 or 3 weeks. This has been of plastic, made according to the standard Army procedure and under the direction of Captain Stanley F. Erpf and Captain Arthur L. Lund

blad of the Dental Corps of the Army of the United States

The prosthesis is not made from an impression of the socket, since that would result in its occupying too much of the available space. Figure 1 shows some variations in the prostheses that have been fitted. In general, the stud is adjusted to fit into the depression and the base around this stud is cut away to allow the edge of the basket to come forward when the socket is turned. Through support of the stud there is considerable relief of pressure on the tissues in the region of the fornices.

It is not absolutely necessary to use a custom made eye with a stud, good movement can often be obtained with a Snellen form. The reason for this is that the movement of the prosthesis is in part due to the change in the shape of the socket when the basket rotates; one side becomes shallow and the opposite side deep and the eye has to move.

The following tabulations were made on the basis of observations on 60 sockets fitted with artificial eyes. Practically all of them were fitted with custom made plastic eyes. It is realized that this small number may not represent a true cross section. The series was collected from the wards without regard to the preoperative condition. It consisted of 20

Fig. 13 Patient 5 months after operation showing depression and movement of socket.

sockets without implants 20 with ball implants and the first 20 with basket implants.

Average motion degrees	No Implant	Ball Implant	Basket Implant
Nasally	19	9	25*
Temporally	3	5	12
Superiorly	25	20	29
Inferiorly	12	20*	30
Total	69	74	109

The sockets without implants showed the greatest variation in movement from patient to patient and those with basket implants the least variation. This is illustrated by the following tabulation:

Fractures having	No Implant	Ball Implant	Basket Implant
45° total horizontal movement	1 of 20	3 of 20	8 of 20
5° total vertical movement	6 of 20	8 of 20	19 of 20

These tabulations do not indicate the action of the oblique muscles which is a prominent feature of the basket sockets. Neither do they indicate the most important characteristic of all that is, the much more rapid response to movement of the muscle cone, with a notable decrease in the time lag as compared with that for the normal eye.

SUMMARY

On the basis of 100 operative procedures, a new type of basket implant for use after enucleation is presented which with a new type of prosthesis, gives more instantaneous movement and a wider range of action. This procedure, combined with use of a plastic retainer eliminates prolapse of implant and shortens the postoperative convalescence period.

RECONSTRUCTION OF ORBITAL FLOOR DEFECTS

ARTHUR E. SHERMAN M.D. Major M.C. A.U.S. East Orange New Jersey

THE floor of the orbit is triangular in shape and is made up largely of the orbital plate of the maxilla. The orbital portion of the zygomatic bone makes up the anterolateral portion and a small portion of the posterior part of the floor is formed by the orbital process of the palatine bone. The anterior margin is thicker and stronger than the remainder of the floor. The inferior orbital fissure is the lateral boundary of the floor and the infraorbital sulcus runs forward along the central portion of the floor from the inferior orbital fissure to the infraorbital foramen which lies about 1 centimeter below the lower orbital margin. The sulcus and foramen transmit the infraorbital artery and the main portion of the second division of the trigeminal nerve that is the maxillary nerve which is known as the infraorbital nerve as it passes into the infraorbital sulcus.

Trauma to the lower orbital margin with resulting fracture of the margin and floor of the orbit not infrequently produces more severe displacement of the thin floor of the orbit than of the thicker and stronger margin itself. The displacement of the floor is usually downward due to the concave orbital surface of the floor anteriorly and because an air space the maxillary antrum lies below the floor. It is Pfeiffer's opinion that fracture of the wall of the orbit is the entire cause for traumatic enophthalmos. Of 53 cases reported by him 24 had a depressed fracture of the floor with out any fracture of the orbital margin. More than half of these were caused by a blow with a fist. Pfeiffer states that in the cases of less severe enophthalmos the posterior portion is fractured and in the cases of more severe displacement the entire floor is broken through. It is surprising how infrequent there is permanent visual damage in these cases. At times severe trauma to and fracture of the supraorbital area may produce an accompanying

depressed fracture of the floor of the orbit due to transmission of the force through the orbital contents. Depressed fracture of the floor may also occur from the explosive force of shell fragments entering the orbit and from actual perforation of the floor by shell fragments or other foreign elements. It is quite unusual to have an elevation of the floor of the orbit unless there has been a severe crushing trauma to the region of the antrum.

A diagnosis of depressed fracture of the floor of the orbit is made on the history of trauma and the presence of depression of the eyeball with some enophthalmos. Diplopia may be present and also anesthesia or hypesthesia over the distribution of the infraorbital nerve. Immediately following the trauma these signs may be masked by edema and orbital hemorrhage. There may even be an initial exophthalmos. Crepitation from air in the soft tissues and palpable displacement of the orbital margin may be evident. Careful stereoscopic x-rays will usually confirm the diagnosis. There may be marked loss of vision due to internal ocular damage or due to compression of the optic nerve by fracture into the optic foramen or by hemorrhage into the optic nerve sheath in the foramen.

When there has been little or no depression of the floor of the orbit no treatment is indicated. When very definite depression is present it should be corrected as soon as the initial reaction has subsided. This is best done by the otolaryngologist by means of a Caldwell-Luc approach with elevation of the depressed orbital floor and moderate packing of the antrum for a day or two. When this is not done a permanent depression of the orbital floor and orbital contents results. Fracture and displacement of the lower orbital margin should also be corrected as early as possible with internal wiring of the fragments or some method of external fixation if necessary.

When there has been a severe compound comminuted fracture of the lower orbital margin it may be necessary to debride some of the

loose bone fragments. This results in more or less subsequent external deformity.

The purpose of any procedure to reconstruct the orbital floor is primarily to elevate the orbital contents. If sufficient correction of this depression is obtained it will also eliminate the sinking or retraction of the upper portion of the upper eyelid and lessen the enophthalmos. In late cases of depressed floor it is not possible to elevate the floor to its normal position because of the firm adhesions which have formed. In the past this has usually been accomplished by the use of autogenous or preserved cartilage grafts to the floor of the orbit under the periorbital. This is the method used by most of the general plastic surgeons during the past few years in the army general hospitals that were ophthalmic and plastic centers. The taking of an autogenous rib cartilage graft makes an additional procedure and at times the pleura has been accidentally perforated. The use of preserved cartilage has been quite satisfactory although it has been demonstrated that preserved cartilage buried subcutaneously produces a typical low-grade foreign body reaction over a period of months and is gradually absorbed and replaced by fibroblastic tissue. Osteoperiosteal grafts from the tibia have also been used. These are used to bridge the defect and usually require temporary additional support by packing in the antrum. Thus, together with taking of the graft, makes a needlessly complicated procedure.

It was our experience at O'Reilly General Hospital and also the experience of ophthalmologists at some of the other army eye centers, that the use of various inorganic materials has been very satisfactory for orbital floor reconstruction with resulting simplification of the surgical procedure.

In June of 1945 at the suggestion of Dr. Reudemann of Cleveland, Lieutenant Colonel Struble at Crile General Hospital used tannum wool and later tantalum mesh to fill in defects of the orbital floor in battle casualties in whom the Reudemann implant eye was being used. Struble stressed the importance of careful preoperative x-ray determination of the size of the defect and received excellent cooperation from his roentgenologist, Lieutenant Colonel Shifflet.

During the latter months of 1945 Captain Souders of Dibble General Hospital used rhomboid shaped plates of the plastic acrylic (methyl methacrylate) to cover the defect of the floor of the orbit in old fracture cases who had some depression of the eyeball. Souders used various sizes and thicknesses of these acrylic plates depending on the amount of depression of the eyeball and size of the defect in the orbital floor. The dissection was made through a skin incision along the lower orbital margin but he placed the acrylic plate on the periorbital and not under it. The plate was held in position by sutures through small holes near the anterior edge of the plate and through the periorbital.

About this same time Major DeVoe of Halloran General Hospital used a packing of glass wool under the periorbital in several cases of depressed floor to fill in the defect and elevate the eye and orbital contents. He reported very satisfactory results and no complications.

In the spring of 1945 at O'Reilly General Hospital we began to use a wedged-shaped acrylic implant to the floor of the orbit to elevate the orbital tissues in cases of anophthalmos who had had an enucleation with small implant in Tenon's capsule, or who had had a

Case 2

Case 3

Fig. 6. Appearance on admission

Fig. 7. Final result.

simple eversion of the eyeball. This procedure proved a quite satisfactory method to eliminate or lessen the retraction or sinking of the upper portion of the upper eyelid. We soon applied this procedure to cases of old fracture of the floor of the orbit with depression of the eyeball and enophthalmos. The acrylic wedges were made in 3 sizes, the average or middle size being about $2\frac{1}{2}$ centimeters by $1\frac{1}{2}$ centimeters and about 8 millimeters thick at one end and tapering down to about 4 millimeters at the other end. The operation is similar to that used by Gilles and others except that the wedgeshaped acrylic implant is used instead of a cartilage graft. After incision through the skin and subcutaneous tissue down to the lower orbital margin, the periorbital is incised and the periorbital thoroughly elevated with a submucous elevator. A wedgeshaped acrylic implant is then placed on the depressed floor with the thick end of the wedge posterior. A large enough implant is used to satisfactorily elevate the orbital contents and two or more implants can be used in cases of severe depression of the floor. Traction sutures in the tendons of the lateral and medial rectus muscle are a great aid in drawing the eyeball upward and forward at the time the wedge is being inserted. The periorbital is firmly closed with No. 000 gut mattress sutures. Subcutaneous sutures should also be used to avoid a depressed postoperative scar. A good pressure dressing is important to prevent or lessen hematoma.

Gilles was one of the first writers to recommend the use of cartilage grafts for replacing loss of bone of the orbital rim. This has been used extensively since that time. Landemann in 1916 first described the use of an iliac bone graft to the mandible and this was later ap-

plied to the malar and infraorbital area by a number of plastic surgeons.

During the past few years tantalum plates, tantalum mesh, and acrylic plates have been used to replace loss of orbital margin. Too frequently the preformed tantalum or acrylic plate does not give the proper contour to the overlying tissues. It is difficult to alter these plates satisfactorily at operation. Also it is not a simple procedure to fashion the plate. Tantalum mesh is easily shaped at the operating table but it does not become firmly attached to the surrounding bone. Rib cartilage grafts do not become attached to the bone and also may change after operation. It was the experience of the eye and the plastic service at O'Reilly General Hospital that these inorganic materials and also cartilage grafts did not give as satisfactory results in reconstruction of the lower or lateral orbital margin or malar area, as did the use of grafts of iliac bone. After removal of most of the cortex the cancellous bone can be easily shaped to fill in the defect properly and give a very satisfactory contour to the overlying tissues. If the ends of the graft rest on exposed bone it soon becomes firmly attached to this bone. A blood supply is rapidly formed into the grafted bone and a cortex or pseudocortex forms on the surface of the graft. Postoperative hematoma will seldom cause trouble if a narrow rubber

CASE 5 (Figs. 10, 11, and 12) Patient was struck in the right orbital area with a large stone and incurred severe compound depressed fracture of supraorbital area and of the floor of the orbit. Debridement of frontal sinus area and repair of lower eyelid performed at another general hospital. Admitted to O'Reilly General Hospital 3 months later. Severe enophthalmos and depression of right eye as well as marked depressed deformity of supraorbital area were present. He had loss of central vision due to traumatic damage to macular area. One month after admission the eye was quite well elevated and the enophthalmos fairly well reduced by means of five acrylic wedge implants to the depressed floor of the orbit. Recovery was uneventful. Two months later an iliac bone graft to the supraorbital area was performed by Lieutenant Colonel Karlson.

CASE 6 (Figs. 13 and 14) Patient incurred a compound comminuted fracture of right zygoma and severe laceration of right eye from shell fragment wound. The right eye was enucleated 3 weeks later and 1 month following that a large cheek flap rotated to fill defect over zygoma region. He was admitted to O'Reilly General Hospital 6 weeks later. There was a long broad depressed scar from lateral lower orbital margin down to angle of jaw with loss of malar eminence and of lateral lower orbital margin. The lateral canthal area was drawn down about $\frac{1}{2}$ centimeter. Three months later an iliac bone graft was used to reconstruct the lateral lower orbital margin and malar area, with excision of much of the scar. Two months later the lateral canthus was elevated by means of a Z-plasty or interposition of flaps.

CASE 7 (Figs. 15, 16, and 17) Patient incurred severe compound comminuted fracture of right zygoma and maxilla with avulsion of lower eyelid and anterior segment of eyeball from shell fragment. The wound was debrided the same day. The eye was eviscerated 5 days later. He was admitted to O'Reilly General Hospital 13½ months later. There was a loss of entire right lower eyelid with conjunctiva and skin adherent to the remains of lower orbital margin. Due to fracture of the floor of the orbit there was marked depression of the orbital contents. Several operations were used to reconstruct the lower eyelid and the area of the lower orbital margin was reconstructed with an iliac bone graft. After the eyelid fissure was reopened the orbital con-

tents were elevated by means of an acrylic wedge implant on the floor of the orbit. A fascia lata graft was used to correct the retraction below the brow.

SUMMARY

Fractures of the floor of the orbit should be reduced soon after injury if feasible.

When late reconstruction is indicated the orbital contents can be very satisfactorily elevated by means of an acrylic implant on the depressed floor. Other materials such as tantalum mesh and glass wool have been satisfactory in the hands of some surgeons.

Small losses of the lower orbital margin can be satisfactorily filled by a fascia lata graft. Larger losses are best reconstructed by a graft of cancellous iliac bone with more consistently good results than cartilage grafts or preformed tantalum or acrylic plates.

THE RECONSTRUCTION OF THE UPPER LID

EDMUND B SPAETH M.D. F.A.C.S. Philadelphia, Pennsylvania

WHEN considering this subject, 'The Reconstruction of the Upper Lid' almost every person who has had experience with ophthalmic plastic surgery will immediately think of some more or less complicated case in the correction of which he had a part. The difficulties and complexities of such individual cases are most stimulating—of this there is no doubt. Nevertheless such cases as all others are corrected through certain basic principles peculiar to the subject, and common to all these conditions.

Regardless of any one technique these principles can be divided into two major subdivisions—when reconstructing an upper lid is a good functioning eyeball present, and is the socket surgically anophthalmic? These two possibilities modify the surgery necessary to a tremendous degree.

A second group of three probable conditions which influence the necessary surgery and contingent upon the first subdivision are the eyelid defects themselves. First, is the deformity under treatment the result of the loss of the external layers of the lid only with normal conjunctiva present second in the case considered are all the structures of the lid both anterior and posterior surfaces, wanting even partly and third are only the posterior lid surfaces and structures predominately deficient?

The presence of an intact functioning eyeball in lid reconstructions compels, without permissible modification the use of conjunctiva or of mucous membrane for the reconstruction of the posterior surface of either lid. The absence of an eyeball, that is surgical anophthalmos, permits the use of epithelium either as a free skin graft or as some type of pedicle flap for replacing the lost posterior surface of the reconstructed lid. The reconstruction of a lid in cases in which no eyeball

is present is a simpler procedure because demands are less exacting. Even the question of later lid motility is relatively insignificant, because corneal exposure and difficulties from that are not a problem. As a matter of fact in many of these cases the ideal result hoped for is that of good looking fixed lids which will retain a prosthesis satisfactorily even though they may be quite immobile.

A third consideration of importance in the reconstruction of a lid especially the upper lid is a thorough knowledge of the rather complex anatomy of this lid. Surgical principles which are harmonious with the anatomy of the upper lid are certain to give much better results than any technique which disregards this anatomy. One must remember that the lid has two major parts—a posterior conjunctival and tarsal plate surface or layer and an anterior muscle and skin layer. The muscle pull of the levator palpebrae superioris is at a right angle to the muscle action of the orbicularis fibers. The two muscles lie in entirely different planes. These two muscles are not only antagonistic, one to the other but both are very active muscles. Last the two cantal angles are themselves quite immobile but here the two muscles have common attachments.

Reconstructive surgery for the correction of defects in the posterior surface of the lids is essentially the reconstruction of a cul-de-sac by means of mucous membrane. Cicatrices may be present simultaneously in the external surface of the lid, which needs reconstruction and resuture but this is a minor part of the surgical procedure. A free graft of mucous membrane sutured into a correcting position is the basic essential (Fig. 1).

This same situation, when present with surgical anophthalmos means a necessary correction either with the same type of graft or by means of a free skin razor cut graft. This must be cut as thin as is humanly possible. In these instances the external surface

Fig 1. Mucous membrane correction of the posterior surface of a defect of the lid.

Fig 2. Simultaneous correction of posterior and anterior surfaces of the upper lid. Prosthesis in position.

Fig 3. The major portion of the upper lid is lost with much cicatrix present. The entire superior cul-de-sac is absent. A pedicle flap from the forehead and a free skin graft to the posterior surface of the lid.

of the lid which is deficient may be corrected simultaneously with either a pedicle flap or a free skin graft. Figure 2 is such a case. The superior cul-de-sac of the deficient socket was corrected by mobilizing the remains of the upper lid still present, swinging these inward upon themselves as a hinged flap to form the new posterior surface of a new lid. At the same time, the anterior surface of this lid was corrected with a free skin graft. It is in this type of case that the use of supraclavicular skin has such impressive successes. Figure 3 is a similar case in which the correction of the external surface was achieved by means of a pedicle flap from the contiguous regions. A free razor cut epithelial graft was placed on the posterior surface of the lid flap. A pedicle flap had to be used here because of the extensive scar in the tissues remaining. To remove all of that meant the removal of almost the entire lid. In general pedicle flaps are to be

used only when necessary, never as an operation of election. When that is so as in this indication there need be no hesitancy about their use. If properly executed the additional scarring which they cause can be held to a minimum often to an amount quite inconsequential. The value of a pedicle flap lies in the ability to transplant larger portions of epithelium under difficult circumstances (anatomic, naturally) with a greater chance for continued viability in the graft than if that same amount of skin had been transplanted freely and without this added means for nutrition i.e. the pedicle.

The ideal reconstruction of an upper lid in the presence of a normally functioning eyeball assuming that both the anterior and the posterior surfaces of the lid have been lost in part depends upon a technique originally advanced by Landolt in 1901 and subsequently carried to even greater general use

Fig 7 The complete correction of the upper and lower lids by an epithelial lined flap

form a smooth lid margin. That tarsus which formerly lay in the lower lid will now be in part, if not wholly, in the upper lid. The conjunctival surface of the two lids is usually quite adequate for good function. Figure 5 is an illustration of this technique. The entire upper lid was not lost but the major part was missing. The illustration in center shows the intermarginal attachments. The curve of that points out rather clearly the total amount of new tissue now lying into this position. The illustration at right shows the new palpebral fissure following its formation—also the degree of closure possible.

In this case the lashes were suggested by a line of tattoo marks at the new lid margin. A hair bearing graft for the eyelashes of the upper lid can be placed into position rather readily prior to the formation of the new palpebral fissure. Such a graft should be taken from the lower edge of the opposite eyebrow cut with beveled edges and sutured into position.

A second technique to be considered under similar circumstances i.e. eyelid defect in the presence of a good functioning eyeball necessitates the implantation of a mucous membrane graft into either the forehead or the upper lid immediately beneath the skin surface, to prepare the necessary graft with a posterior mucous membrane layer which will function as conjunctiva. This graft either as a free graft or as a pedicle flap is then transplanted to its correcting position for the simultaneous reconstruction of both the conjunctival and skin surfaces. Figure 6 shows the utilization of this basic principle by means of a pedicle flap. Mucous membrane covers the posterior surface and epithelium the anterior surface. Some of the principles of Wheeler's halving operation will apply in the utilization of this technique. This is so because those principles of Wheeler's are basic with ophthalmic plastic surgery whenever accurate car-

entry is necessary in lid surgery. They are not characteristic of any individual procedure.

The mucous membrane to be used is taken from the buccal mucosa trimmed to maximum thinness wrapped over a mold, and then buried into a pocket prepared for it. After this has taken surgically any portion of the mucous membrane may be transplanted with any amount of epithelium needed. In the instance shown a certain portion of the lid remains were rearranged and utilized by scar resection and by suture. The case was one of postmalignancy reconstruction. Somewhat less than one-half of the lid was still wanting following that. The mucous membrane epithelium pedicle flap was quite sufficient for a good correction. That portion of the rather conspicuous mucous membrane still present upon the skin of the lower lid had to be removed and the area covered with a skin graft. Skin from the supraclavicular region or from the opposite upper lid are equally satisfactory for this.

Hughes carried out this principle of combined mucous membrane epithelium graft by implanting the mucous membrane into a pocket of the opposite lid. Skin and mucous membrane were then transplanted as a free graft. Even though this technique was successful for the lower lid and perhaps should be

Fig 8. An epithelial lined pocket on the face prior to transplantation for a new upper lid.

Fig. 9. A, left, Deformity of upper lid corrected by scar resection and resuture, also with a necessary enucleation. B 3 months following surgery

recommended for that, the use of a flap is better for an upper lid repair

The complete correction perhaps better expressed as correction for the more or less complete loss of an upper a lower or of both lids, in the absence of an eyeball is similarly done but with epithelium rather than with mucous membrane. A pocket of epithelium is formed on the forehead or beneath the skin of the upper face. Following that one may transplant a flap having two epithelial surfaces, an anterior and a posterior surface thus making possible correction for the complete loss of one or more lids. The principle is quite like that described in detail for the use of mucous membrane but the absence of an eyeball permits the use of epithelium for the posterior surface of the new lids. Figure 7 illustrates such a case before and after its correction. Figure 8 shows a pocket upon the face before transplantation to an upper lid.

In this presentation the only cases considered for the explanation of the rules for lid reconstruction were those in which there had been a loss of soft tissue to such an extent that the replacement of these tissues was necessary for the correction of the case. Many cases could be presented wherein the correction was obtained by simple (meaning uncomplicated and not ease of performance) scar resection resuture and the reposition of those tissues still present to correct the plastic defect present. Figure 9 is such a case. The necessary enucleation of the phthisical eye had little effect upon the condition of the lid. Scar removal and suture were responsible for the satisfactory result obtained. This possibility as a surgical principle must be remembered in the

Fig. 10. A, left, Extensive ectropion following herpes, the lids opened and closed. B Correction with a razor cut free skin graft.

consideration of cases for correction. It is properly included herein considering the title of the paper and the scope of its subject matter.

RECAPITULATION AND CONCLUSION

In this presentation such defects as ectropion entropion symblepharon etc., have not been the basic conditions under consideration. The extent of pathology possible in some of these conditions, however as illustrated in Figure 10 might permit one to consider this degree of deformity worthy of the term—lid reconstruction. It is, nevertheless only a case of extensive ectropion and as such is to be corrected by procedures rather well established for this type of condition.

The real purpose of the paper has been to outline the principles underlying lid reconstructions, and especially when applied to the upper lid. The different anatomic possibilities which present themselves for correction differ so decidedly in their demands and hence in the permissible surgical techniques available for correction that it was thought necessary to emphasize again that basic fact.

These surgical principles as they have just been discussed are the result of clinical experience and as such they should be seriously considered as these cases appear for correction.

THE MANAGEMENT OF NONMAGNETIC INTRAOCULAR FOREIGN BODIES

HARVEY E. THORPE, B.Sc. M.D. F.A.C.S. Pittsburgh Pennsylvania

THE character of intraocular foreign bodies coming to the ophthalmic surgeon's attention has changed materially in recent years. Formerly 95 to 98 per cent were magnetic, leaving a bare 2 to 5 per cent of cases to which the magnet was not applicable. Now some series of cases are reported in which the nonmagnetic percentage runs as high as 10 and even 40 per cent.

The ratio of nonmagnetic to magnetic intraocular foreign bodies was always higher in battle casualties than in civilian life. This ratio took a sharp rise with the nefarious introduction by the Axis forces of nondetectable nonmagnetic land mines in the North African Desert campaigns as reported by Stallard (16). The World War II experience of the United States Army Medical Corps is well described in Wilder's report, that out of 150 enucleated eyes received at the Army Institute of Pathology 89 harbored nonmagnetic particles.

The increased use of alloys containing copper, aluminum, brass, lead, zinc, manganese, nickel, etc. in industry as well as war thus presents new and difficult problems. In addition to these one runs across eyes harboring glass, plastics, coal, stone, sand, lashes, grit, wood, and other substances.

Our miracle tool the magnet is worthless in application to nonmagnetic substances. Nor does it attract steel alloys containing considerable manganese. Often the ophthalmologist was thus made to despair on seeing a patient with a nonmagnetic intraocular foreign body. New simplified and improved x-ray and other localization methods with improved surgical techniques have made it possible to save some of these eyes from blindness. Several problems present themselves when one is called to attend a traumatized eye.

1. How shall one proceed in the average case of ocular injury?

2. When should an intraocular foreign body be suspected?

3. How much damage has been done to vital structure?

4. Is a foreign body present within the eye and how can we readily localize it accurately?

5. How does one differentiate the nonmagnetic from the magnetic foreign body?

6. To what extent does infection complicate the picture and how shall we control it?

HISTORY

The ophthalmologist should investigate the possible presence of an intraocular body in every case of possible injury and especially in uveitis. The history is most important. The examiner must question the patient in detail about the likelihood of exposure to injury while hammering, chiseling, or working with rotating or moving machinery. One should note whether the patient was near flying particles or near an explosion or in proximity to shattering solids. An investigation of the tools and substances in use at the time of accident gives a clue as to the likelihood of the intraocular particle being magnetic or otherwise. It also may tell us whether the fragments are glass or stone, or copper, or steel, etc.

Stallard (16) writing of his North African war experiences found a clue to the nature of the intraocular fragments by examining small particles lodged in the skin of the lids and face. U.S. Army ophthalmologists have examined injured eyes which contained more than one particle, some magnetic and others nonmagnetic. Close questioning of the patient may further reveal the size of the fragment and its course of flight toward the eye. The lapse of time since injury is necessary to ascertain fragments that have been in contact with soil may harbor tetanus bacilli. These and a host of other details may be elicited by a careful history. Previous negative examinations or the story of removal of a superficial corneal

Fig. Course of foreign body through the globe and trauma caused to a, cornea (perforation) b, iris (arrow points to hole) c, lens (tract through it) d, Section of globe showing tract of particle, location of foreign body and vitreous opacities due to hemorrhage e, Foreign body lodged in retina, as viewed with ophthalmoscope.

particle should not lead us astray. There are many cases on record dismissed with a pat on the shoulder which later turn up with siderosis or chalcosis or a cyclitis due to an intraocular foreign body.

THE EXAMINATION

Both eyes must be examined subjectively and objectively. One may find evidence of disease, of injury or even of sympathetic ophthalmia. Visual acuity and field examination of each eye where possible should be followed by complete examination with all the instruments and methods at our command. The anterior segment must be studied with loupe and oblique illumination, with ophthalmoscope, with the transilluminator and particularly with the slit lamp microscope. The cornea, the conjunctiva, the sclera, the anterior chamber, the iris, the lens, the vitreous, the entire visible retina and the optic nerve must be painstakingly scrutinized. If photophobia or pain interfere a drop of local anesthesia such as tetracain 0.5 per cent may facilitate the examination. A perforating wound in the cornea as evidenced by a hole in Bowman's and especially in Descemet's membrane leaves permanent telltale evidence. A hole in Descemet's membrane or in the iris leaves permanent evidence. Discovery of such, however minute is proof of a penetrat-

ing wound and charges the examiner with an exhaustive study to establish the presence of an intraocular foreign body and to localize that foreign body.

The value of exhaustive routine examination is evident from the next 2 cases cited.

CASE 1. A.T., mechanic, aged 30 years, complained of occasional discomfort and redness of the left eye. Routine examination revealed a minute perforation of Descemet's membrane. A history of injury 6 months previous while chiseling was finally elicited. The patient remembered that a foreign body was removed from the conjunctiva by a fellow workman. Since then his eye watered in bright light, etc. The first x ray examination was negative. A second x-ray examination by Vogt's soft tissue technique revealed a minute fragment near the iris root. With the aid of gonioscopy it was possible to visualize the foreign body covered by exudate in the lower anterior chamber angle. The particle was subsequently removed and the eye quieted down.

CASE 2. J.B. Auto repairman, aged 34 years, referred with 24 hour old perforation of his left eye by a piece of wire. Examination revealed a left corneal perforation in the pupil zone with swollen traumatic cataract bulging into the anterior chamber.

Vision of the right eye was 20/35. Slit-lamp examination of that eye revealed early siderosis and a healed lumbus perforation. X ray examination of both eyes located a small irregular metal splinter in the right ciliary body. The left eye was negative roentgenologically.

Further questioning revealed a history of injury 9 months previous while working on another job. The first aid attendant and the plant surgeon found no foreign body at that time and since there was no pain and very little redness the eye was dismissed as negative at that time.

The examination gave evidence of 3 distinct injuries involving both eyes: the fresh perforation of the left eye without foreign body; a forgotten injury of the right eye (proved to harbor a small steel splinter). A magnet extraction was performed by the anterior route on the right eye. The left eye was atropinized and watched for several days after which a linear cataract extraction was performed.

ROENTGENOGRAPHY AND LOCALIZATION

With the clinical examination completed one proceeds to x ray examination and localization. Accurate localization is the *sine qua non* for the proper management of intraocular foreign bodies. It is best to look up a roentgenologist who takes special interest in foreign body localization. It is good policy for the ophthalmologist to be thoroughly familiar with x ray foreign body localization. He should be

able to supervise the localization and he should be able to suggest variations in the technique so as to determine whether a fragment is in or just outside the eyeball. Glass (unless containing lead) wood and many other substances are not opaque to x rays. Metallic and stone splinters are x ray opaque. But a minute foreign body can be overlooked. Sometimes artefact shadows are produced by imperfect screens. Because of this it has been our practice to advise first qualitative study by (a) stereo-x ray in posteroanterior view with patient's chin and nose resting on the x ray cassette (b) lateral stereo of the affected eye, (c) skeleton free (soft tissue) technique of Vogt (28-29) for minute fragments in the anterior segment (see Figs. 1-2). The latter is performed by pressing the corner edge of a dental film into the inner canthus and shooting across from the temporal side with the central x ray beam (soft ray). This can be done with the eye looking successively in various directions namely up straight ahead down abducted and adducted as necessary. This exposes all portions of the anterior segment. The eyelids may be pulled out of the way by adhesive strips. A small metal marker attached to the upper and lower limbus at 12 and 6 o'clock helps orientation. Proptosis produced by injecting retrobulbarly 2 to 4 cubic centimeters of 2 per cent procaine aids in exposing more of the globe to this skeleton free soft tissue technique. Thus, some substances such as glass or minute metal splinters, which would be obscured by bone shadows and would not show up by the usual technique, become visible by Vogt's method.

Fig. 2. Vogt's skeleton free x ray technique for localization of foreign bodies in the anterior segment of the globe. Plate tube distance 30 inches equals 75 centimeters.

Localization is readily performed by Comberg's method (2-12). This method is simple and accurate when properly applied. It is foolproof for it indicates automatically voluntary or involuntary rotation of the eyeball away from the desired position.

A drop of 0.5 per cent pontocaine is instilled in the conjunctival sac.

A contact lens with 4 lead markers on the limbal sclera is inserted beneath the eyelids so that the raised portion fits over the cornea. The lens is rotated so that the lead markers are at, or nearly at the 3, 6, 9 and 12 o'clock meridians.

First a posteroanterior exposure is made with the patient in prone position (chin and nose resting on cassette to throw the petrous pyramid shadow below the orbit) (Figs. 4-6). The patient looks straight ahead so as to see a reflection of his uninjured eye in the cassette or in a small pocket mirror lying on the cassette before the uninjured eye (Fig. 4a). The central ray (perpendicular to the plate) is aligned with the anteroposterior (visual) axis of the globe. In the presence of strabismus a thin

cover glass mounted on a black cardboard triangular wedge is used as an angle mirror to reflect a pocket flash light into the noninjured left fixating eye (Fig. 3). The light is held so that the visual axis of the injured right eye is perpendicular to the x ray plate. The central ray must pass coaxially with the visual line of the injured eye. If one eyed the patient is instructed to look at the reflection of his eye in the polished cassette surface. If this is not possible due to low visual acuity the angled cardboard mirror and flash light are employed before the only eye. Then a lateral exposure is made with the patient lying on the affected side and looking straight ahead at a mark on the opposite wall. The central ray should pass through the limbal plane bisecting the cornea (Figs. 5-7).

The measurements taken from the posteroanterior and lateral views are corrected for distortion by reducing them by 10 per cent. They are then plotted on Comberg's localization chart (Fig. 8). In the posteroanterior view (Fig. 6) the lead dot shadows are connected diagonally by lines scratched on the x ray plate to give the center of the cornea. A line, ab drawn through the foreign body and the corneal center c makes angle ϕ with a line

drawn parallel with the roofs of both orbits. The angle is measured with a protractor and transferred to the localization chart (Fig. 8)—and is shown to correspond with the 120 degree meridian. The distance from foreign body to visual axis on x ray plate (Fig. 6) corrected for x ray distortion by 10 per cent is plotted on this circular front view.

From the lateral exposure (Fig. 7) one determines the distance of the foreign body from the limbal plane along the line, cd . The anterior and posterior limits, 13.8 millimeters and 16.6 millimeters respectively are plotted on the meridional section of the eye through the 120 degree meridian. The radial distance—foreign body to posteroanterior axis—is taken from (Fig. 6) as plotted on (Fig. 8a) and is again plotted on (Fig. 8b). This corresponds with its position in the upper temporal quadrant of the posterior vitreous. One can readily realize that a movement of the globe would be shown by a corresponding change in position of the localizing shell. (Figs. 6 and 7 show exposures with a glass contact lens.)

There are several objections to the Comberg contact lens. It does not always lie centered on the cornea and being made of glass can break on falling.

cover glass mounted on a black cardboard triangular wedge is used as an angle mirror to reflect a pocket flash light into the noninjured left fixating eye (Fig. 3). The light is held so that the visual axis of the injured right eye is perpendicular to the x-ray plate. The central ray must pass coaxially with the visual line of the injured eye. If one-eyed the patient is instructed to look at the reflection of his eye in the polished cassette surface. If this is not possible due to low visual acuity the angled cardboard mirror and flash light are employed before the only eye. Then a lateral exposure is made with the patient lying on the affected side and looking straight ahead at a mark on the opposite wall. The central ray should pass through the limbal plane bisecting the cornea (Figs. 5-7).

The measurements taken from the posteroanterior and lateral views are corrected for distortion by reducing them by 10 per cent. They are then plotted on Comberg's localization chart (Fig. 8). In the posteroanterior view (Fig. 6) the lead dot shadows are connected diagonally by lines scratched on the x-ray plate to give the center of the cornea. A line ab drawn through the foreign body and the corneal center c makes angle ϕ with a line

drawn parallel with the roofs of both orbits. The angle is measured with a protractor and transferred to the localization chart (Fig. 8)—and is shown to correspond with the 120 degree meridian. The distance from foreign body to visual axis on x-ray plate (Fig. 6) corrected for x-ray distortion by 10 per cent is plotted on this circular front view.

From the lateral exposure (Fig. 7) one determines the distance of the foreign body from the limbal plane along the line, cd . The anterior and posterior limits, 13.8 millimeters and 16.6 millimeters respectively are plotted on the meridional section of the eye through the 120 degree meridian. The radial distance—foreign body to posteroanterior axis—is taken from (Fig. 6) as plotted on (Fig. 8a) and is again plotted on (Fig. 8b). This corresponds with its position in the upper temporal quadrant of the posterior vitreous. One can readily realize that a movement of the globe would be shown by a corresponding change in position of the localizing shell (Figs. 6 and 7 show exposures with a glass contact lens.)

There are several objections to the Comberg contact lens. It does not always lie centered on the cornea and being made of glass can break on falling.

be done by such methods. Nor are such tests conclusive. The magnet should be applied only in the operating room and then only after x ray localization. The sideroscope was in use in the latter part of the 19th century to determine the magnetic character of foreign bodies. It was unreliable and fell into disuse.

Since 1943 I found the Berman locator especially valuable in determining whether an intraocular foreign body is magnetic or nonmagnetic. It has been useful in locating and pinpointing the spot on the sclera closest to the magnetic fragment. It has served as a check on x ray localization (which is usually correct and occasionally faulty). It has made possible the determination as to whether the fragment has actually moved after magnet application. It has helped me to decide whether the giant magnet or the hand magnet was necessary for extraction of a foreign body. It has served as a psychological comfort throughout the operative procedure. It was first used by Moorhead at Pearl Harbor in 1941. Minsky published the first recorded application of the locator for the transscleral removal of an intraocular foreign body. So far it has not aided in localizing small nonmagnetic fragments.

JUDGMENT AS TO PROCEDURE

Having determined the character and having localized the foreign body, having determined the absence or presence and extent of infection, having arrived at some conclusions as to the amount of ocular trauma and having come to the conclusion that some measure of vision can be saved, one asks himself: which foreign bodies should be removed and which might best be left undisturbed?

Chemically inert substances such as glass and stainless steel do not cause ocular irritation as a rule. Aluminum is also well tolerated. On the other hand brass, copper, zinc and their alloys, iron and steel produce ocular inflammation and deterioration. One must use careful considerate judgment in deciding on operative interference.

Prompt removal of an intraocular foreign body before it sets up too much irritation or infection and before it becomes surrounded by exudate is essential. It is wise to attempt the removal of all irritating nonmagnetic foreign

bodies, if one can avoid excessive mutilation of the globe in doing so. Prompt and early surgery followed by a well considered plan of procedure should be the rule. The surgeon with all facts at hand decides whether operative interference or conservative treatment is to be followed. Should surgery seriously threaten the integrity of the eyeball and prove to be mutilating or destructive, then one must realize that nothing is to be gained by performing an operation.

COMBATING INFECTION—PROPHYLAXIS

Every early foreign body case, when first seen, must be considered as potentially infected. To combat such infection and before any organism can be isolated, the surgeon must rely on prophylactic measures. Since the days of Wagner Jauregg's malaria treatment of syphilis, ophthalmologists have found that foreign protein therapy in the form of 15 to 30 million typhoid bacilli antigen intravenously or 10 cubic centimeters of boiled milk intragluteally are helpful in controlling intraocular inflammation. On admission 1500 units of antitetanic serum is given. Penicillin—100,000 units—is given intramuscularly as an initial dose and is repeated in 50,000 unit doses every 3 hours for 4 to 6 days. We have also found subconjunctival injection of 500 units of penicillin dissolved in 0.5 cubic centimeter normal saline to be helpful.

Sulfadiazine has been especially valuable in our experience in combating infection. Six grams are given during the first 24 hours beginning with a 2 gram dose. Four grams are then given daily in divided doses for another 48 hours. Thereafter 2 grams are given every 24 hours for 5 days. A blood level of 8 to 10 milligrams is desirable. The urine must be watched for sulfadiazine crystals. The blood must be watched for leukopenia and anemia.

PREOPERATIVE CARE

As preparation for local anesthesia, pentobarbital 0.1 gram is given 1 hour before operation. The skin is scrubbed with soap, irrigated and painted with 3% per cent tincture of iodine or merthiolate.

Local anesthesia is performed in the following manner:

Fig. 9.

Fig. 9. Modified Comberg localizing shell made of plastic or glass. It may be anchored to episclera at 3 suture holes.

Fig. 11.

points and serrations on blade, c, lateral view illustrating backward pointing serrations. They afford a strong grasp.

Fig. 11. Kuhnt's method of removing penetrating corneal splinter pupil zone, aided by use of forceps.

1. Pontocaine hydrochloride 0.5 per cent is instilled topically 3 drops at 1 minute intervals.

2. Procaine 2 per cent with 1:30,000 epinephrine is injected into the lateral canthus subconjunctivally and into the superior rectus tendon.

3. Akinesia is performed by injecting 5 cubic centimeters of 2 per cent procaine, containing 1 minim of 1:1000 epinephrine 10 to 15 millimeters anterior to the incisura intertragica (ear notch).

4. Retrobulbar injection consists of 0.5 cubic centimeter solution, containing cocaine hydrochloride 1 per cent, procaine 2 per cent, epinephrine 1:30,000.¹

CORNEAL FOREIGN BODIES

Superficial foreign bodies may be wiped off with a moistened cotton applicator after topical anesthesia. Imbedded particles are dislodged with a sharp spud used to pry up the edge of the fragment. Multiple imbedded foreign bodies are readily removed with the 1 millimeter curet.

The narrow beam of the slit lamp microscope is invaluable in ascertaining the depth of a corneal foreign body. It readily affords information as to whether a particle is wholly intracorneal or projects into the anterior chamber. Metallic shivers or wooden splinters between the corneal lamellae are removed by dissecting down on them and then prying them

¹To prepare procaine 2% with 1:30,000 epinephrine, add 1 minims of 1:1000 epinephrine solution to c.c. of 2% procaine solution.

up with a cataract knife. When somewhat dislodged the splinter is grasped with the author's corneal splinter forceps (22) (Fig. 10). This forceps has fine rasped teeth which point backward and provide an excellent hold. Thorns and wood splinters are likely to cause keratitis if removed incompletely. On the other hand small glass spicules or coal particles or powder particles if wholly intracorneal may be left undisturbed since they rarely irritate.

The more troublesome corneal foreign bodies are the ones penetrating to or into the anterior chamber. There is always danger of pushing them into the chamber also the hazard of producing traumatic cataract if the projecting fragment strikes the lens capsule.

Penetrating corneal foreign bodies in the pupillary zone are best removed by the method suggested by Kuhnt many years ago (Fig. 11). Pilocarpine is used to contract the pupil. A narrow keratome (4 mm. wide) such as that of Agnew or of Castroviejo is introduced through the cornea and the point anchored on the other side. The keratome blade thus lies beneath the foreign body. One now dissects the corneal layers down to the foreign body and removes the fragment with the splinter forceps. The keratome is now withdrawn and the pupil is dilated with atropine. The anterior chamber is restored with normal saline to avoid anterior iris synechia.

A penetrating splinter in the periphery is removed after making a corneal flap inserting 1 or 2 interrupted sutures (Fig. 12). The flap is lifted and the foreign body is removed with

Fig. 12.

Fig. 12. Limbal incision and preplaced sutures for removing peripheral placed penetrating corneal splinter.

Fig. 13. Second step in removal of splinter from everted cornea with forceps.

Fig. 13.

forceps from within (Fig. 13). It may be necessary to pry the splinter loose with a knife needle.

Another method for removing deep corneal foreign bodies is to make pressure from inside with a small Reverdin needle (inserted through a keratome incision) against the posterior surface of the cornea while cutting down onto the foreign body (Fig. 15).

FOREIGN BODIES IN THE ANTERIOR CHAMBER

Magnetic particles in the anterior chamber rarely require the insertion of an instrument into the globe, except for toilet of the wound. On the other hand, the nonmagnetic fragment must depend on special forceps: a blunt iris hook, and an Elschnig spatula for its removal. Small particles of glass, coal, inert solids, and rootless lashes do not as a rule require surgery. Copper and brass must be removed.

Fig. 15. Use of Reverdin needle through keratome incision to press foreign body backward through cornea while extraction is attempted from without.

Fig. 14.

Fig. 14. a, Use of blunt iris hook to dislodge fragment wedged in chamber angle. Final removal with forceps. b, Forward incision in cornea permitting access into chamber angle.

It has been our practice to use the Berman locator in every case, and on occasion we found an intraocular foreign body to be magnetic, when the history suggested otherwise. The penetrating corneal foreign body is at times pushed into the anterior chamber and then it is obviously handled as such.

For the operation one should have at hand the usual iridectomy instruments, plus serrated curved anterior chamber dot forceps, Arruga's capsule forceps, the author's corneal splinter forceps, Tyrrel's blunt iris hook, Elschnig's cyclodialysis spatula, and an anterior chamber irrigator. It should be a rule to fill the anterior chamber with normal saline at the end of the operation. Hyphema should be allowed to absorb or must be irrigated away before removal can be attempted.

Nonmagnetic foreign bodies not enmeshed in iris tissue are readily grasped and removed with one of the above special forceps through a properly placed keratotomy. It is best to avoid the wound of entry unless it is large. The corneal incision should be posterior to the foreign body so that the rear wound lip will not interfere with instrumentation. The particle should be grasped so that it will not dart away. The lens capsule must be avoided. After removal of the fragment, any iris prolapse that may be present is replaced, the chamber is then restored with saline and in most cases it is advisable to close the incision with atraumatic silk sutures. This prevents postoperative iris prolapse. No atropine is instilled at this time. A binocular occlusive dressing is applied. After 3 or 4 days, a per

carried out under direct vision with greater ease; (2) it is possible to ligate the main gastric artery at its exact origin from the celiac axis, thus insuring complete lymph node excision; (3) it enables the surgeon to resect the tail of the pancreas and the spleen if this becomes necessary; (6) it shortens considerably the operative time, which is a desirable feature; (5) should a total gastrectomy become necessary, the visualization of the jejunal blood supply and the performance of the esophagojejunal anastomosis are made more easily.

After the necessary anastomosis has been effected, the incision is closed layer by layer. The diaphragm is repaired with interrupted silk sutures and the enlarged opening is sewn to the transplanted stomach. Before the chest wound is closed, a rubber tube is inserted in the 9th interspace for underwater drainage. The costal arch is repaired by approximating the cartilages with chromic catgut. Before the abdominal incision is closed, a Witzel jejunostomy is done for feeding purposes. A properly applied snug dressing completes the operation.

The relative comfort of these patients as compared with those who have had rib cutting and rib excision operations is very impressive. It seems to me that the postoperative course is smoother and more rapid. We have, up to the present writing, employed this incision on fourteen occasions and have become more impressed with each succeeding case. I believe that its more general adoption will simplify considerably the problem of carcinoma of the cardia and lower esophagus.

THE PROBLEM OF STRESS INCONTINENCE AND ITS SURGICAL RELIEF

W. E. STUDDIFORD, M.D., F.A.C.S., New York, New York

THE past fifty years has witnessed a very full development of specialization in medicine. Among the fields which have tended to become separated in the process are those of urology and gynecology, so that many present day gynecologists have little or no experience in urological problems; the average urologist is in no better position in regard to gynecology. This situation is unfortunate since the bulk of urologic disorders peculiar to the female are fundamentally due to gynecological factors. Occupying a prominent place among such urological conditions is the symptom of stress incontinence due to urethrocele. The fact that this condition lies at the border line between two specialties may account for the common lack of understanding of its nature and to the slow progress of its surgical relief.

Stress incontinence in the female, under conditions which raise intra-abdominal pressure, such as sneezing, coughing, lifting heavy weights, or, in extreme cases, any exertion, is a common gynecological symptom. In most instances it is of occasional occurrence and can be considered only a minor annoyance. Under these conditions most patients conceal this symptom and admit to it only under direct questioning (20). In a minority the symptoms develop to such a degree that the patient, on the slightest exertion, discharges a large amount of urine. Such patients are continent only when lying down or sitting quietly; their disability, therefore, becomes a subject of major complaint. It is with this extreme degree of incontinence that this report is chiefly concerned, particularly if previous efforts at surgical cure have resulted in failure.

Reference to gynecological texts of the late nineteenth century reveal that this condition, then termed passive incontinence, was regarded as most difficult of relief (13). Prom-

inent in the treatment was a varied and wholly irrational group of drugs, as well as different types of physiotherapy. Surgery was mentioned as a possible treatment with the very faint recommendation that it was usually unsuccessful. Dudley (4), in his presidential address entitled "Incontinence in Women" before the American Gynecological Society in 1905, summarizes the therapeutic knowledge of a somewhat later period. He mentions four main types of treatment: (1) injection of paraffin in the region of the urethra; (2) massage and electricity; (3) torsion of the urethra (180° - 450°) as advocated by Gersuny; and (4) advancement of the external urethral orifice, advocated by Pawlik, Hemmelfarb, Aliberran, and others. He condemned the first three forms of treatment as being useless or dangerous, but saw some merit in the last, describing an advancement operation which he himself had devised. It is of interest in this regard that Berkow recommended advancement of the external urethral orifice as recently as 1941, reporting 17 cures in 21 cases, although it is difficult to see how such a procedure would restore an incompetent internal sphincter (2). In addition Murless reported successful results following the injection of sclerosing solutions about the urethra in 1938 (15); therefore, these old forms of treatment have not been completely abandoned. It is probable that the procedure advocated by Kelly in 1913 (4, 8) and utilized by him during the preceding 10 to 12 years, was the first operation directed at the cure of stress incontinence and practiced extensively in this country. The successful results of this technique, commonly known as the Kelly stitch and still widely used, were at first attributed to the tightening of a relaxed internal sphincter. Following the introduction of this operation, various modifications were developed, involving more extensive dissection and often plication of the dilated bladder neck and upper

urethra as well as the supporting fascia (3, 7, 20). The most recent of these operations, devised by Kennedy, includes a mobilization of the upper urethra by separation of the lateral fascial attachments from the pubis (10, 11, 12). During this period it was realized that the most important aim to be attained by surgery was the reapproximation of the fascial supports of the bladder neck so that this structure was held securely behind the symphysis (3, 20). When such a result was accomplished the previously atonic sphincter regained its tone and once more became competent. Unless support was attained the bladder neck and upper urethra would once more prolapse to form a urethrocele, and the incontinence would recur because of the consequent loss of sphincter tone.

While successful results are attained, in a majority of instances, by utilizing the residual tissues—particularly if the incontinence is of slight degree—all operators report failures. These range from 20 per cent, as reported by Kelly (9), to the recent figure of 7.1 per cent reported by Kennedy (12). While no accurate figures can be reported, it is believed that the percentage of failures in our own clinic fall somewhere between these figures. Once a failure has occurred further operations of the same type are apt to be unsuccessful. This tendency may be illustrated by one of the cases about to be reported:

No. 8523-43 Mrs. J. V., aged 38 years, tripara, quadrigravida, was admitted to the gynecological service, Bellevue Hospital, on February 20, 1943, for the fifth time, with a chief complaint of stress incontinence. In her first pregnancy in 1924 she was delivered by forceps at home after a labor of 5 days. Her symptoms date from this event. Full term pregnancies occurred in 1927 and 1933, and a 3 month spontaneous abortion in 1935. She first sought surgical relief for her incontinence in 1930. At this time a diagnosis of cystocele, relaxed vesicle sphincter and relaxed perineum was made. The cystocele was repaired, the Kelly technique was employed to tighten the vesicle sphincter, and a perineorrhaphy was performed. No improvement in the incontinence occurred although her pelvic supports were adequately restored. In 1933 a second attempt to control the symptom was made, utilizing the same procedure except that perineorrhaphy was found to be unnecessary. Again complete failure was the result. In 1940 a third attempt was made utilizing the technique described by Kennedy. Again, failure was the result. Six months later, in the same year, a

fourth attempt was made to help her by the implantation of a strip of fascia lata under the bladder neck. No noticeable improvement followed.

Results such as this frequently cause the gynecologist to assume the attitude that nothing further can be done to relieve the patient.

Today the problem of urethrocele with stress incontinence lies in the surgical relief of patients who have experienced operative failures and in the avoidance of such failures. If the facts underlying this condition are correct there are three possible explanations for these failures: first, that the operative procedure has been inadequate; second, that the healing process has been imperfect due to infection or faulty blood supply; and third, that the supporting tissues have once more given way under the continued assault of intra-abdominal pressure. The first explanation often can be discarded since failures occur in the hands of experienced operators using procedures which appear fundamentally correct. Of the second and third explanations the last appears the most likely since serious infection is rarely seen in operations on the anterior vaginal wall, and in most failures temporary relief is obtained only to be followed by a recurrence of the condition.

Since the last supposition appears to be the explanation of most failures the reinforcement of the residual fascia by transplanted tissue would seem to be a possible answer to the problem. Such an attempt has been made by several gynecologists, utilizing muscle and fascia from several sources. The best known of these operations is that termed the Goebell-Frangenheim-Stoeckel procedure, in which, following a plastic repair of the bladder neck, strips of rectus fascia and underlying muscle are transplanted behind it (5, 6, 16). This operation never has been performed widely in this country. Others have reinforced the lower urethra with transplanted tissue (14, 19), although such a procedure would not be expected to have favorable results. Interest in the value of fascial reinforcement was stimulated by the report of Aldridge in 1942 on the use of transplanted strips obtained from the aponeurosis of the oblique muscles in combination with a plastic operation on the upper

urethra and bladder neck (1). He had obtained complete relief in a patient with stress incontinence who had been operated upon twice previously without success. Since then he has obtained favorable results in several similar cases.

Impressed by the result reported by Aldridge, a study of the application of this principle was undertaken. Since 1943 transplanted abdominal fascia has been utilized in a group of 44 patients to reinforce the repaired supports of the bladder neck and upper urethra. Thirteen of these cases have already been reported (17, 18). The present report includes this group and an additional 31 cases since operated upon. The etiological factors may be summarized as follows: There were 2 cases of congenital origin, 1 not influenced by full term delivery but suffering from congenital lues, and the other made worse by full term delivery. There were 25 cases of traumatic origin. Of these 16 cases were immediate, within 2 years of delivery and 9 were remote, more than 2 years after delivery but under the age of 40 years. There were 16 cases of traumatic and involutional origin—10 cases at time of menopause and 6 cases remote from menopause. Only 1 case was of purely involutional origin, a nullipara aged 70 years. That urethrocele may be of congenital origin is not commonly realized. The available labor records were reviewed, and it was found that a surprising number of the preceding deliveries had taken place without obvious injury. Often great care had been expended to preserve the perineum. This fact suggests that the forward projection of the presenting part in the second stage by the intact perineum often may be the traumatic agent. If this is true, the performance of an adequate episiotomy should obviate the occurrence of such an injury.

The most frequent lesion found on examination was the uncomplicated urethrocele which was present in 25 patients. This finding was mainly due to the large proportion of patients in this group who had undergone previous plastic operations (13 cases) with otherwise satisfactory results. Particular attention should be called to the group of patients who, in addition to urinary incontinence, showed indications for pelvic surgery. In 9 cases the

urethrocele was complicated by additional forms of relaxation, in 1 case 2 previous operations had failed to relieve the incontinence and in 8 cases there had been no previous surgery. In 10 other cases the urethrocele was complicated by additional forms of relaxation and by indications for hysterectomy. In 2 of these, 3 previous operations had failed to relieve the incontinence and in 8 cases no previous surgery had been performed.

Some may quarrel with the use of this procedure in so many primary cases. It can only be stated that in each instance there appeared to be a factor that made the possibility of failure by other methods seem likely. Among such factors were the age, the extent of the relaxation, and the character of the residual pubocervical fascia. For example, in this group was a nullipara, aged 69 years, with marked stress incontinence of 1 year's duration and a well developed urethrocele; also a 31 year old woman with a large urethrocele, apparently of congenital origin, who had suffered from incapacitating stress incontinence during her entire life. In the group requiring abdominal surgery, it was a matter of few moments to add the fascial reinforcement to the plastic operation previously performed.

In 15 of these patients the procedure described by Aldridge was used in a slightly modified form. Follow-up has revealed successful results in 11, but failures have resulted after a brief interval in 4 cases, accompanied, in each instance, by a recurrence of the urethrocele. Nevertheless the relief of most of these patients, most of whom had experienced one or more previous operative failures, was convincing evidence that the underlying principle was correct.

Experience with the Aldridge technique has shown several disadvantages. It involves (a) two changes in position; (b) the simultaneous performance of abdominal and vaginal operators, and because of these complexities (c) an increased opportunity for lapses in surgical asepsis. Most important, there appeared to be no way to fit accurately the fascial strip to the bladder neck. Frequently, because of shortness the strips had to be brought together under marked tension. In spite of the latter defect, union took place in

some patients quite unexpectedly. In others separation of the strips is suspected as the cause of the subsequent failure. The final disadvantage lay in the fact that the procedure was awkward to utilize if indications for reinforcement of the residual fascia was discovered unexpectedly at the time of a plastic operation on the bladder neck.

Because of these defects this type of operation was abandoned and another technique was adopted. This has been used on 30 patients, including 1 in whom a failure had resulted from the modified Aldridge procedure. It may be described as follows.

TECHNIQUE

The patient is put in the lithotomy position, prepared, and draped. The labia minora are retracted laterally by means of stay sutures. A weighted speculum is placed in the vagina thus exposing the lower anterior vaginal wall. In many of these patients previous operative procedures have resulted in adequate support to the portion of the bladder adjacent to the upper vagina and cervix. As a result of the previous perineorrhaphy the cervix may be difficult to draw down or expose. Since the necessary dissection is about the upper urethra and bladder neck, such exposure is not necessary. The anterior vaginal wall is seized with two Allis clamps, placed as far lateral from the midline as possible and at as high a level as can be attained. A third Allis clamp is placed in the midline about 1 centimeter from the urethral orifice. The scars of one or more previous operations can often be seen on the anterior vaginal wall (Fig. 1). The vagina is held tense by lateral traction on the first pair of clamps and a transverse incision is made between them through the depth of the wall. Scissor dissection at the lateral portion of this incision defines the plane between the bladder and the lower anterior vaginal wall, following which the scar in the midline can be divided without any risk of injury to the bladder neck or urethra. The lower anterior vaginal wall is then divided in the midline at right angles to the first incision. The edge of the vaginal wall on each side is seized by Allis clamps. Traction downward on these clamps and traction upward on the

clamp placed near the urethral orifice aids greatly in freeing the vaginal wall from the urethra and in making this incision. It should be carried to a point about 1 centimeter from the urethral orifice. The upper anterior vaginal wall can then be freed for a distance of 1 to 2 centimeters from the bladder and incised in the midline, Allis clamps being placed on the edge of the freed wall. The combined incisions result in the exposure of a diamond shaped area under which lie the upper urethra and bladder neck. The plane of the supporting fascia of the upper urethra and bladder neck is then identified, a varying amount of sharp dissection being necessary (Fig. 2).

Once found, the plane of separation along the outer aspect of this fascia can usually be followed by blunt dissection with the finger outward and upward to its line of attachment along the inner aspect of the superior pubic ramus (Fig. 3). Moderate pressure at this point with the finger results in rupture of the attachment allowing the finger to enter the space of Retzius. Occasionally penetration of the lateral part of the fascia must be accomplished by scissors. This dissection is carried out on each side. The bladder neck and upper urethra are thus fully mobilized. Considerable bleeding may accompany the latter stages of the dissection due to rupture of veins about the bladder neck. Since the source of bleeding is inaccessible it is fortunate that it invariably ceases spontaneously after a short interval. The supporting fascia of the upper vagina and bladder neck is then plicated by means of interrupted mattress sutures. The number of sutures required varies from one to three. This results in an elevation of the bladder neck behind the symphysis and a consequent lengthening of the urethra. A Penrose drain, measuring at least 30 centimeters in length, is then placed with uterine forceps so that an end lies in the space of Retzius on each side of the bladder, the midpoint of the thin tubing lying just underneath the bladder neck (Fig. 4). The excess vaginal mucosa is then excised in the form of four triangles, the tissue traumatized during the operation being removed. The vaginal wall is then closed with interrupted sutures from below upward, taking great care not to in-

clude any of the underlying tissue or the drain itself. A self-retaining catheter is placed in the bladder (Fig. 5).

The patient is then put in the dorsal position, prepared with merthiolate and draped. A long suprapubic incision is made curving to the left of, and extending slightly above, the umbilicus, exposing the external rectus sheath (Fig. 6). The incision is then draped with towels and clips. The rectus sheath at the bottom of this incision is cleared of fat to a width of 1.5 centimeters. The sheath is then incised just to the right of the midline, the incision being carried across the midline and just to the left of the umbilicus in the upper part of the wound. The septum between the two sheaths is cut and the fascia is then freed from the inner margin of the left rectus muscle to a depth corresponding to the area cleared of

Fig. 2. Vaginal incision completed. The plane between the pubocervical fascia and the vaginal wall has been defined by sharp dissection.

Fig. 3. The plane between the pubocervical fascia and vaginal wall has been followed upward and laterally to the pubic attachment by means of blunt finger dissection. The lateral fascial attachment is ruptured thus allowing the finger to enter the space of Retzius lateral to the bladder neck.

Fig. 4. The pubocervical fascia has been approximated in front of the bladder neck and upper urethra by means of interrupted mattress sutures. This elevates the bladder neck behind the symphysis and lengthens the urethra. As a result the bladder neck lies at a much higher level than is depicted in this drawing. One-half of a Penrose drain, 30 centimeters in length, has been placed in the space of Retzius on the left side. With a uterine forceps the operator is preparing to place the opposite half in the space of Retzius on the right side. The midpoint of the drain will lie under the bladder neck when the tubing is fully in place.

Fig. 5. Four triangles of vaginal wall have been excised. The vaginal incision is closed with interrupted sutures, with care not to include any of the underlying tissue or the Penrose drain.

fat on its external surface. The length of such a strip has always been found to be more than sufficient. Too short a strip is a handicap which cannot be overcome. Great care must be taken in separating the rectus sheath from the underlying muscle at the lineae transversae, one of which is always found close to the umbilicus and sometimes another 2 to 3 centimeters below it. The muscle is closely attached to the sheath at these points and unless the separation is made carefully the fascia will be weakened enough to break on moderate traction. At this point the peritoneum can be opened, and any necessary surgery can be accomplished. If a complete hysterectomy is performed the upper prevesical fascia can be tightened if necessary by interrupted sutures or by excising a V shaped portion of upper anterior vaginal wall and ap-

Fig. 6, left. Small inset shows character of skin incision. To left, the midline incision has been made just to right of midline. The external surface of the left rectus sheath has been cleared of fat and the septum between the sheath has been cut. The strip of fascia to be mobilized is outlined. The peritoneal incision has been closed following the completion of intra abdominal surgery.

Fig. 7. The fascial strip has been mobilized, its lower end being attached about a centimeters above the symphysis.

proximating the cut edges with interrupted sutures, as advocated by Meigs. The peritoneum is closed after the completion of the pelvic operation. The mobilized rectus sheath on the right side of the incision is then freed by cutting from above downward along the left margin of its cleared surface (Fig. 7). The lower end is left attached about a centimeter above the symphysis. One of the pyramidalis muscles is frequently left attached to its internal surface. The anterior wall of the bladder with its pad of fat can now be separated from the posterior aspect of the symphysis. The ends of the Penrose drain are easily located on each side of the bladder neck and are withdrawn from the lower angle of the wound (Fig. 8). Traction on either end is sufficient to make the drain move easily through the tunnel under the bladder neck. The end of the fascial strip is placed inside the open end of the left arm of the tubing and secured with a ligature. This step makes a smooth joint which will not catch on any tissue. Traction on the right arm of the drain carries the strip about the bladder neck and out of the lower angle of the incision. The strip can then be secured to the margin of the lower right rectus

sheath, by several interrupted sutures (Fig. 9). It should fit snugly about the bladder neck but should not be tight. The ligature securing the strip to the Penrose drain can now be cut, and the drain removed. The bellies of the rectus muscles are now approximated in the midline with three or four interrupted sutures. Several retention sutures are placed. The aponeurosis is carefully closed by two continuous sutures, one starting at the lower angle of the defect, the other at the upper. The two sutures meet at midportion of the incision where they are tied. The skin is closed with continuous dermal suture; a bolster is placed along the line of the incision, over which the retention sutures are tied. The use of sulfonamides in the wound has been abandoned.

After experience with both methods, it is believed that this procedure possesses definite advantages: (a) it is simpler, requiring only one change of position of the patient; (b) the plastic and abdominal surgery are consecutive and not simultaneous, reducing the number of assistants required; (c) breaks in aseptic technique are less likely to occur; (d) the fascial strip can be more accurately fitted to the

Fig. 8, Left. In inset, the bladder has been freed from the upper aspect of the symphysis. The ends of the Penrose drain have been located on each side of the bladder neck and have been delivered from the lower angle of the wound. The free end of the fascial strip is being introduced into the open end of the Penrose drain on the left. In the drawing proper the strip has been secured to the drain by a transfixion ligature, thus forming a smooth joint. It is being drawn around the bladder neck by traction on the right arm of the drain.

Fig. 9. The free end of the strip has been sutured to the right rectus sheath by interrupted sutures, thus forming a sling under the bladder neck. This sling should be snug but not tense. The Penrose drain has been removed. The abdominal incision may now be closed, great care being taken with the lower angle.

bladder neck; (e) the line of suture in the strip is remote from the undersurface of the bladder neck and at a point where all strain upon it from intra-abdominal pressure should be reduced by one-half; (f) any indicated lower abdominal or pelvic surgery can be carried out during the course of the operation; (g) it can be utilized without prior plan, if the residual supporting tissues are found to be attenuated during a plastic operation on the bladder neck.

POSTOPERATIVE CARE

After operation the patient is given 0.5 gram of sulfadiazine four times a day until the catheter is removed or until spontaneous voiding occurs. The catheter is irrigated once a day. It is removed on the ninth postoperative day, when the retention and skin sutures are taken out. No wound infections of major degree have been encountered. Two patients developed hematomas of the abdominal wound which required evacuation.

The resumption of normal voiding has been found to be much more delayed following this procedure than after the Aldridge type of operation. In the 15 patients operated upon by the latter technique 10 voided on the ninth day or before. Only 5 patients were unable to void following the removal of the catheter and

all were voiding normally by the fourteenth day. In the 29 patients upon whom the present technique was carried out (including 1 patient reoperated upon, and excluding 1 who developed a fistula) only 5 voided immediately following the removal of the catheter; 16 were voiding 1 to 5 days later; 5 went 6 to 11 days; while 3 took even longer, 1 of whom was successful 23 days after the removal of the catheter. Various measures were undertaken to hasten the return of normal urination but none were notably successful. Cystoscopic examination of one of the most protracted cases showed no distortion of the bladder; in another there appeared to be a moderately elevated bladder neck. Since all patients eventually regained their ability to empty their bladder normally it would appear that many of them, having existed with a hair-trigger mechanism, sometimes for years, took time to learn to void after the bladder neck had regained stability. This long delay in the recovery of normal bladder function in a few of these patients proved to be a disadvantage from the point of view of prolonged hospitalization and because these individuals became greatly disturbed because of their disability.

These patients have been carefully followed. When successful results are attained,

the frequency and urgency of urination, often present 4 to 6 weeks after operation, disappear gradually. Usually no urinary symptoms are reported at the second visit which is made about 2 to 3 months later; the bladder neck is found tight behind the symphysis, with little or no descent on straining or coughing. When the bladder neck descends, incontinence will reappear and a failure result. Of the 15 patients operated upon with the modified Aldridge technique 11 (73 + %) have shown satisfactory results; 7 (46 + %) of them have been perfect, while 4 (26 + %) still experience occasional slight loss of urine on extreme effort. The latter patients are satisfied and are unwilling to undergo further surgery. With the present technique 27 (90%) successful results have been attained in 30 patients; only 1 (3 + %) of them states that she still has slight stress incontinence on extreme effort. Of the entire group 38 had total successful end-results, 86 per cent.

In regard to the failures, an opinion has already been expressed as to the defects of the procedure suggested by Aldridge. These are believed to be responsible for some of the failures following the use of this method. Of the 3 failures (10%) following the use of the present technique, 2 appear to be due to disruption of the reinforced support with recurrence of the urethrocele. One occurred because of a bladder neck fistula, caused by faulty dissection. Almost certainly the plane of cleavage between bladder and fascia was followed rather than the plane between fascia and vaginal wall. In addition the strip was pulled through the tunnel with narrow gauze packing which proved unsuitable because it caught in tissue. All of these errors can be avoided and should not recur if careful technique is followed. This fistula has been finally closed after one suprapubic and three vaginal operations, and it is regrettable to say that condition of the patient today is identical to her original state. One of the patients on whom the present technique was used developed a hernia of the lower angle of the abdominal incision. Extreme care must be used in the suture of this area because it is the most difficult part of the wound to bring into apposition.

The operative procedure described here is not presented with any idea of supplanting the widely used methods which employ a reconstruction of the original support of the bladder neck. The cases which have been described by no means represent the total number of patients with the symptom of stress incontinence operated upon during the same period. When the usual type of plastic procedure is employed an attempt is being made to predict its success or failure on the basis of age of the patient, degree of atrophy, the character of the residual pubocervical fascia, and the presence of factors producing excessive intra-abdominal pressure. It is only by learning how to make such an evaluation successfully that the failure of the usual plastic can be anticipated, thus avoiding the necessity of one or more secondary operations.

The results attained by reinforcing the reconstructed pubocervical fascia with transplanted abdominal fascia have not been free from failure. The majority of such failures have occurred during the evolution of an operative method. Most of them appear to be due to a defective technique rather than to an error in principle. The full technique, which has been described, has been utilized in the last 25 cases, successful results being attained in all patients with primary or recurrent urethroceles. The 2 failures both occurred in patients who had developed stress incontinence for the first time following the performance of extensive plastic operations. Four such patients were encountered in the entire group. No obvious explanation can be given for the difficulty in attaining a surgical cure in this type of case.

It is believed that the effectiveness of the procedure is dependent equally on a careful dissection and repair of the anterior pubocervical fascia and the support and reinforcement of this area by the fascial sling. The initial repair elevates the bladder neck behind the symphysis and restores the urethra to its normal length. The sling should increase the elevation of the bladder neck slightly, relieving the tension on the reunited pubocervical fascia; in healing it becomes incorporated in the pubocervical fascia, reinforcing the vulnerable area at which a recurrence of the

urethrocele can take place. It has been suggested that the sling causes a kink or stricture of the upper urethra, but no evidence of the latter has been found during postoperative catheterization or cystoscopy.

The permanence of the successful results can be determined only by prolonged follow-up. The first patient in whom the transplanted fascia was used was operated upon almost 3 years ago and shows a stabilized bladder neck with no tendency to descent. She is the patient whose history of four previous surgical failures has been quoted. It is to be hoped that the remainder show an equally good record.

SUMMARY AND CONCLUSIONS

1. The present day problem of the woman suffering from urethrocele and its accompanying symptom, stress incontinence, consists of:

a. The development of a method of surgical relief which will prove effective when simple plastic procedures have failed;

b. The evaluation of primary cases in regard to factors which may predispose to the failure of simple plastic procedures;

c. The use of a more effective operation in primary cases on the basis of such criteria, in order to anticipate failure by the simpler methods.

2. A surgical technique has been presented which it is hoped may solve this problem in some degree.

TWO HUNDRED AND FIVE CASES OF CANCER OF BREAST TREATED BY RADICAL MASTECTOMY

PAUL STIRLING PUTZKI, M.D., F.A.C.S., and JAMES H. SCULLY, M.A., D.Ed., M.D.,
Washington, District of Columbia

MANY valuable studies of cancer of the breast have been reported by large clinics where the statistics are usually based on the collected experiences of many. This is a report of 205 cases of cancer of the breast in which radical mastectomy, management, and follow-up have been carried out by an individual. All of these cases are from private practice. In most instances the patients were first seen by the referring practitioner. There has been no selection of our cases. All cases with adequate records, proof of diagnosis, and good follow-up have been included.

This study serves to emphasize the necessity for early diagnosis as well as to point out other factors which may influence the final results. All diagnoses are based on the microscopic examination of paraffin sections of tissue removed from the involved breast. In no case was aspiration biopsy tissue used as a means of diagnosis. In the management of the cases complete histories were obtained and complete physical examinations were made. In some cases information on these points was furnished by the referring practitioner; consequently, in such cases additional history and physical examination relative to the breast only were obtained. If metastasis was suspected, a preoperative roentgenogram of the chest or a metastatic series was made. Preoperative roentgen therapy was used in selected cases, but this was not a routine procedure. In all cases the basis of treatment for this disease was radical mastectomy. Postoperative roentgen therapy employed immediately upon recovery was carried out as a routine. The patients have been followed by office visits every 4 months, at which time a

thorough history was taken and physical examination was made. Patients who had not visited the office for over 9 months were communicated with by telephone or correspondence. Simple mastectomies performed as a palliative measure for advanced carcinoma of the breast on elderly women, for foul smelling lesions, in severe cardiac disorders, and chronic debilitating lesions were not included in this series.

In this paper we wish to discuss the symptoms, physical examination, operability, treatment, pathology, irradiation therapy, metastatic lesions, and final results.

SYMPTOMS

Table I enumerates the chief complaints or presenting symptoms noted. A lump in the breast was almost universally noted; in 88 per cent in our series. Many women complained of enlargement, swelling, soreness and pain in the breast. In most cases these findings were associated with a breast lump. Pain which attracts attention to so many conditions was present in only 31 cases. Sixteen women complained of discomfort in the breast. Pain in the breast occurring during the menstrual period is usually due to a benign condition. A stabbing, lancinating pain associated with a lump and slight tenderness frequently indicates that the lesion is a cyst. A dull ache or heavy feeling and discomfort may be due to a cancer. Pain in the breast may be due to pregnancy, mastodynia, abscess, mastitis, tuberculosis, involution, nipple disturbances and reflexly from pelvic pathology. There were 13 women who desired examination because of recent trauma to the breast. In all of these cases a malignant mass was discovered. It was felt that the trauma was coincidental and only served to focus attention upon the already diseased breast. Of course,

From the Department of Surgery, George Washington Medical School and the Department of Pathology, Georgetown Medical School.

TABLE I.—SYMPTOMS NOTED IN 205 CASES OF CANCER OF THE BREAST

Symptoms	Number	Per cent
Lump or mass in the breast	181	88.3
Enlargement or swelling of the breast	35	17.1
Pain in the breast	31	15.1
Soreness of breast	24	11.7
Discomfort in breast	16	7.8
Trauma to breast	13	6.3
Retraction of nipple	9	4.4
Discharge from nipple	9	4.4
Recent weight loss, more than 10 pounds	8	3.9
Annoying sensations in breast	6	2.9
Ulceration of skin of breast	4	2.0
Tenderness of breast	4	2.0
Itching of nipple	3	1.5
Itching of breast	2	1.0
Dimpling of skin of breast	2	1.0
Swollen arm	2	1.0
Eczema of the nipple and areola	1	0.5
Patients with two or more symptoms	104	50.7

we also have seen numerous traumatized breasts with no evidence of cancer.

Nipple discharges and crusting were mentioned by 9 women, one of whom tolerated the discharging nipple for 1 year. Eight women complained of rapid weight loss along with other more vague symptoms. Examination revealed a malignant breast tumor. There were 18 patients in this series who did not have breast symptoms or complaints. This is in conformity with the fact that early stages of infiltrating mammary cancer may be symptomless. There may be no pain, no discomfort, no enlargement of the breast. Therefore, the absence of tell-tale symptoms or the presence of a silent small, innocent-appearing lump in the breast must not lead us into false security. One hundred and four women presented two or more leading symptoms. The most frequent combination was a lump in the breast together with recent enlargement of the lump, pain or soreness.

Table II presents a time analysis of the 181 patients who complained of a lump or mass in the breast. Notwithstanding the seriousness of this, 36 of these women knowingly carried a lump in their breasts for 2 years or more without consulting a doctor; whereas, only 19 presented themselves for examination within a month after discovery of the breast tumor. On the other hand, an elderly woman had a breast lump 18 years and only because of

TABLE II.—LENGTH OF TIME THE LUMP HAS BEEN PRESENT IN THE BREAST—181 CASES

Lump in breast	Number	Per cent
Less than 1 month	19	10.5
One month to 2 months	40	22.1
Three to 6 months	26	14.4
Six to 9 months	35	19.3
Nine to 12 months	25	13.8
Two years	14	7.7
Over 2 years	22	12.2

recent rapid growth or enlargement of the lump did she consult a doctor. In 53.4 per cent a breast lump had been present longer than 6 months.

Even after we have discovered the breast tumor, either large or small, we cannot be certain of its age or extent of growth. We can be certain of the true nature of the tumor only by a microscopic examination after the tumor has been removed. Therefore, all tumors should be excised and microscopic study should be made to determine whether malignant change is present.

The knowledge of a breast condition was present in all these cases because the patients were either referred by practitioners or the patient was conscious of the breast condition herself. The fact that the lump had often been present in the breast for many months before treatment re-emphasizes the need for cancer education, for frequent periodical examination of the breast by the practitioner and for immediate pathological investigation.

Prognosis is definitely related to the presence or absence of glandular involvement, consequently, early diagnosis and early operation are most important. More than one-half the cases, 54.6 per cent, presented evidence of glandular metastasis at the time of operation. This is a high percentage of metastasis and it indicates that we are seeing some patients too late in the course of the disease to expect the best results from surgical treatment. Of these patients 62.9 per cent were between the ages of 40 and 59 years. Only 25.9 per cent were 60 years or more. The fourth decade was most frequently involved as well as the decade which had the highest percentage of metastatic involvement. In this series the fourth decade was the most vulnerable.

The 2 youngest patients were each 26 years of age.

TABLE III.—AGE DISTRIBUTION OF 205 CASES OF CANCER OF BREAST IN WHICH OPERATION WAS PERFORMED

Age	Number	Percent	With glandular involvement		Without glandular involvement	
			Number	Percent	Number	Percent
15 to 20	3	1.5	1	0.5	2	1.0
20 to 29	20	9.8	11	5.4	9	4.4
30 to 39	65	31.7	30	19.0	35	22.7
40 to 49	64	31.2	33	18.5	31	22.7
50 to 59	41	19.5	18	8.8	23	10.7
60 to 69	12	5.8	5	2.4	7	3.4
70 to 79	1	0.5	0	0	1	0.5
Total	205	100.0	112	54.6	93	45.4

One was a single girl with a massive painful tumor in the right upper quadrant of the right breast. A radical mastectomy was performed. The microscopic diagnosis was scirrhous carcinoma. There was no metastatic involvement of regional glands. She was given postoperative x-ray therapy to the breast and glandular regions (10 treatments to each of 4 portals). She was not castrated nor given hormonal therapy. She married within a year. She is well and in excellent health 4½ years after surgery.

The second girl was married and had 1 child 18 months of age.

She had a small, hard, painless nodule in the upper hemisphere of the left breast. Left radical mastectomy was done and the pathological microscopic report showed scirrhous carcinoma, duct cell type, without glandular involvement. She was given postoperative x-ray therapy to the breast and glandular regions. Ovarian function was not inhibited by surgery, roentgen ray, hormones, or other means. After 4½ years, she is well, in excellent health, and leading a normal life.

With regard to the position of the tumor in the breast, we found that well over 50 per cent were in the upper hemisphere and that the majority of these were in the upper outer quadrant of the breast.

The right breast was involved in 86 cases, 47.7 per cent. The left breast was involved in 94 cases, 52.3 per cent. The frequency of right or left breast involvement has no bearing upon the prognosis of the disease.

Complete information concerning hormonal therapy which patients may have received prior to mastectomy was not available.

Table IV shows that 78 per cent of our cases were married women and 21.4 per cent were

TABLE IV.—CANCER OF THE BREAST—205 CASES

	Percentage

unmarried. There were 65 per cent who have borne children and 34.4 per cent who were childless. Complete information on lactation and nursing was not available. These figures are relative and not a true index of what can be expected in the population at large.

PHYSICAL EXAMINATION

A thorough history of the condition can be diagnostic or misleading. In itself a history is not sufficient. A physical examination of the breast must be done. There are no special types of patients nor special types of breasts with propensities for cancer of the breast. Cancer may occur anytime after puberty.

For the purpose of examining breasts a special room was set up. This includes a reclining chair which permits easy examination of the patient in various positions. A dark room permits transillumination and lighting for shadow effects. There are also facilities for aspirations, redressings, and so on.

The breast is first inspected with the patient exposed to the waist. One breast is always compared with the other as to appearance, size, shape, and regularity of outline. Any changes from the normal may be due to a pathological condition. Flattening, dimpling, or wrinkling of the skin may be brought out by oblique lighting, shadow effects, by having the patient raise her arms overhead while casting low intensity light across the breast. Restricted mobility of the mass or fixation to the skin is due to atrophy of overlying or surrounding fat and fibrous attachment of the mass to the skin, fascia, or underlying muscles. Retraction or elevation of the nipple to one side is suggestive of cancer. The condition of the nipple is observed. It may be crusting, ulcerated, or discharging. Discharges from the nipple may be bloody, serous, white and greenish. Microscopic examination from nipple discharges are made to determine if red blood cells are present. Chocolate colored discharges which sometimes occur in chronic

mastitis could be erroneously described as bleeding from the nipple. In papillary eystadenoma there may be a bloody discharge from the nipple resulting from an intracystic hemorrhage. A cystadenoma may be confused with a carcinoma because it occurs in the third and fourth decades. It is a hard, nodular, painless mass which is opaque to transilluminated light. It is movable and usually does not have the fixation of cancer. It is generally centrally located and feels deep within the breast on palpation, whereas, carcinoma feels superficial on palpation. Trauma to the breast may produce a hematoma with bloody discharge from the nipple simulating a tumor. In 13 cases of this series the trauma was to a pathological breast; consequently, nipple discharges could be misleading if it was assumed that the discharge was due only to trauma. In most cases, however, it is a normal breast which is traumatized. Bloody discharges may be due to a duct papilloma, duct cancer, or cancer starting in the acini. The bleeding is spontaneous and intermittent and associated with a hard, solid tumor. It may also be due to sarcoma, Paget's disease, cracked nipple and trauma. Discharges other than bloody are frequently seen in mastitis, abscess, involutional cysts and other conditions. Greenish discharges may be seen after lactation due to inspissated milk. A whitish discharge may be due to milk, pus, cysts, or malignant growth. Any discharge from the nipple may be serious, thus a careful examination of the breast and the discharge is necessary to determine the presence of a tumor. Often surgery will be required to determine the exact nature of the lesion.

Palpation may be done both with the flat of the hand and the tips of the fingers. Hard nodules which can best be appreciated with the flat of the hand are often scirrhus carcinoma. They may be fixed to the deep fascia and later to the skin. Local flattening or general shrinkage of the breast may be noted. Local flattening suggests cancer; whereas, focal prominence suggests a benign tumor or cyst. Slight dimpling of the skin due to lymphatic edema often occurs early. Changes in the position of the nipple or in the appearance of the skin overlaying the tumor are usually late signs in mammary cancer.

Involvement of the large milk ducts is responsible for fixation and later actual indrawing of the nipple. Retraction of the nipple is very suggestive of early duct cancer or advanced carcinoma elsewhere. Drainage from the nipple is rarely seen in early cancer.

Cysts are round, smooth, fluctuant, well circumscribed and not fixed. Fibroadenoma may be round, smooth, hard, and palpated best with the tips of the fingers. Cancer is hard, irregular, and adherent to neighboring tissue. Early deep abscesses of the breast can be confusing. There may be no elevation of temperature and only slight redness of the overlying skin. They may respond to chemotherapy or they may have to be incised and drained. The abscess gives the feeling of diffuse deep tumor. Undue manipulation, palpation, and squeezing of the breast does not aid in diagnosis and adds the danger of producing metastasis.

TRANSILLUMINATION

Normal tissue transilluminates well. Cysts filled with clear or cloudy fluid and small tumors transilluminate various degrees of light. Blood vessels, bleeding tumors in which there is usually a cyst filled with blood, are opaque to transilluminated light. Dilated ducts distended with inspissated secretions, thick walled cysts, solid tumor, carcinoma, and fibroadenomas over 2 centimeters in diameter will cast shadows. Small malignant or benign tumors may not cast a shadow. Breasts are best transilluminated with patient in the sitting position; however, other positions may yield more satisfactory results in some cases.

We have not used the roentgen-ray soft tissue technique for diagnostic purposes in breast lesions. In some cases the roentgenologists have carried out this procedure for their own edification. For our purposes we did not feel that these procedures have been sufficiently developed to justify clinical use, particularly when microscopic examination would be performed in any case.

In most cases of anticipated radical mastectomy a roentgenogram of the chest and skeleton was made to check for possible metastasis. The x-ray findings were considered in the determination of operability.

Aspiration biopsy, that is, the withdrawing of tissue for microscopic diagnosis, was not employed. It was felt that this was not an adequate procedure because the diagnosis was not always reliable. Aspiration of fluid in benign cystic conditions has been performed but is not considered in this paper.

OPERABILITY

In this series the types of lesions and the criteria of operability were as follows:

1. Any lesion of the breast which clinically appeared to be carcinoma and in which this diagnosis was confirmed by gross appearance and frozen section or the Terry stain.
2. Any cancer of the breast with or without axillary nodes unless the nodes were large and fixed to the surrounding tissue.
3. Any lesion which was freely movable from the thoracic wall regardless of ulceration.
4. Lesion which showed no evidence by roentgenogram of metastatic involvement of viscera or skeleton.
5. The chance of curing the patient or offering comfort and a greater length of life must be reasonably assured.

The pathological findings contraindicating operative treatment were:

1. Roentgenographic evidence of skeletal or visceral metastases.
2. A palpable, large, nodular liver.
3. Large growths which were fixed to the thoracic wall.
4. Extensive metastases to axillary lymph nodes, supraclavicular nodes and other regional nodes, and to other parts of the body.
5. Fixation of axillary glands with edema of the arm.
6. Signs indicating far advanced disease.
7. Skin metastasis beyond the area of the tumor.
8. Bilateral breast carcinoma.
9. Diffuse types of malignancy if at all advanced.

The decision to operate is a matter of experience and judgment. No arbitrary set of rules can be set forth and adhered to without flexibility. The justification has been found in patients who were considered hopeless but following operation have enjoyed many comfortable years.

TREATMENT

Every patient deserves the benefit of treatment. Although we have had no operative mortality we believe that no patient should be subjected to operative treatment, risk, and disfigurement without having the diagnosis definitely proved by a preoperative biopsy and microscopic examination. The final results of treatment will depend upon the extent of the lesion at the time of operation, the thoroughness with which the operation is performed and this includes axillary cleaning, the age of the patient, and the grade of malignancy.

Small lesions of the breast without glandular involvement are most favorable for treatment. Larger lesions with glandular involvement are less favorable. With the advance of metastasis we approach the inoperable stage.

Radical mastectomy followed by postoperative roentgen therapy was the basis of treatment in this series.

In selected cases preoperative roentgen therapy was used. In some instances it produced a false security. The tumor disappeared under the irradiation and the patient refused to proceed with surgery. Let us cite one such experience:

Mrs. E. A., a prominent and intelligent woman of 33 years, the mother of a 6 year old child came to us with the complaint of a lump of 2 years' duration, in her left breast. The mass was symptomless. About 2 months before her visit the mass became larger with a puckering or dimpling of the skin over it. Clinical examination revealed a hard, irregular, freely movable, superficial mass about 2 by 2 centimeters with orange-peel type of skin over the mass and fixed to the mass. The tumor was opaque to transilluminated light. There was a small freely movable, left axillary lymph node. A roentgenogram of the chest was negative. The clinical diagnosis was carcinoma of the left breast with axillary metastasis.

Under preoperative roentgen therapy, which was started the following day, the mammary tumor and axillary node disappeared. The roentgenologist stated: "We thought because of the small dose of x-ray necessary to bring this about that we were dealing with mastitis."

With the disappearance of the tumor the patient refused to proceed with surgery. She did consent to follow-up visits for about 1 year. Then she refused to submit to further observation because she considered herself cured. Within another year and less than 2 years from the time we first saw her, she had extensive metastasis to the bones. She was having much pain and great discomfort. The same roent-

genologist then stated "We are obviously dealing with a type of malignancy." It was now too late to give her any aid through surgery. She went right on to die.

Preoperative roentgen-ray therapy adds to the discomfort of the patient and produces a long delay before operative treatment can be instituted. It is often 4 to 6 weeks during which time metastasis may have its start. In some cases a pleuropulmonitis has been produced. A positive diagnosis of cancer cannot always be made, particularly in early cases. One is not sure what the true condition is. Alleged cures may not have been cures at all. Tolerance of the patient for additional irradiation may be unnecessarily lowered by giving treatments to unproved conditions thus hindering further postoperative treatment. If preoperative irradiation is to be undertaken after biopsy tissue of the tumor has been removed, the surgeon would do better to proceed with radical mastectomy rather than to close the incision, then to proceed with irradiation, and again later return to surgery.

To obtain biopsy material by incision the patient is prepared as for a radical mastectomy. The arm of the affected side is held on an arm board at 90 degrees' abduction. Under pentothal gas anesthesia the incision to secure biopsy material is made. The tumor, with a good sized margin of normal tissue and overlying skin is excised without squeezing, manipulating, clamping or spilling it. The gross section is examined with the pathologist present. A typical cut section of the gross specimen of scirrhous carcinoma, and such growths comprised the type of tumor found in most of our cases, showed a grayish, irregular, firm, gritty mass which was firmly adherent to the surrounding tissue and which sent fibrous streaks shooting into the fatty tissue. The section may be homogenous or it may show the pale yellow dots and streaks of necrotic cells. The cut surface is usually concave. Small cysts are infrequently seen.

Frozen section or Terry stains of the specimens are made immediately. If the microscopic diagnosis reveals a benign lesion, surgery consists of excision of the tumor. If the pathologist reports a malignant growth, surgery consists of radical mastectomy.

The technique of radical mastectomy has been fairly well standardized since the turn of the century. Individual surgeons have employed variations of technique and thoroughness in removal of tissue. In our clinic the operation consists of the amputation of the breast, together with the removal of the pectoralis muscles and a clean dissection of the axillary and subclavicular region. The entire mass is removed *en bloc* to safeguard against transplantation of malignant cells; such transplantation may occur by traumatic or mechanical dissemination of cells within the operative field. Intravenous fluids are not employed during operation or subsequently, as a rule. In no case was severe shock seen at the time of the operation or later.

The type of incision utilized and the amount of breast tissue removed depend on the location of the tumor in the breast, type of breast, size of the breast, and the bodily build of the patient. A wide skin incision is essential if local skin recurrences are to be avoided. Wide superficial and deep fascial removal is likewise important. Many recurrences come from this fascia. All skin around the breast and as much as possible about the tumor are removed. In some cases wide skin grafting has been necessary.

It has been wisely said that one surgeon should be charged with the most radical removal of the tumor and another should be responsible for the closure of the wound; thus the thoughts of closure would not hamper the operating surgeon in the radical excision of tissue. Generally, we have employed a transverse elliptical incision encircling the breast and extending from the posterior axillary line about 10 centimeters below the axilla to the lower midsternum. A second incision at right angles to the transverse incision is carried upward to the shoulder about 3 centimeters medial to the anterior axillary line. This incision provides good mobility of the arm with very little limitation. With this type of incision we have had no axillary cicatricial contractions. Painful contracting scars can be produced by irradiation as well as by improperly placed incisions. Edema of the arm as an aftermath has seldom occurred. Transient and intermittent slight edema of the arm due

to lymph blockage has occurred and this is expected. Thorough cleaning of the axilla will produce some lymph edema. Venous obstruction which may result from pressure on the axillary vein by scar formation has not occurred. The incision permits the maximum removal of skin about the breast. It provides desirable exposure of the axilla which aids in thorough axillary cleaning, removal of the pectoralis muscles, and cleaning of the chest wall. It aids in getting good closure and prevents cicatricial tissue formation in the anterior fold of the axilla. Elliptical incisions along the anterior axillary fold as well as other types of incisions have been used but only in cases in which the transverse incision has not been applicable. The skin incision is made into the subcutaneous tissue, and the flaps are dissected free by undercutting close to the skin to prevent local recurrences and deposits of cancerous cells in the superficial lymphatics.

Hemostasis has been secured by means of plain catgut ligatures or by electrocoagulation of bleeding points. The latter method reduces the operative time. About the same amount of serous fluid has been collected in the wound by either method.

The pectoralis major is severed at its attachment on the humerus and then is separated from the clavicle and retracted downward and medially. The coracoclavicular fascia is incised and the pectoralis minor muscle is severed at its insertion on the coracoid process. This muscle and the pectoralis major are then retracted downward, thus exposing the axilla. The dissection of the axilla is begun at its apex, progressing from above downward removing fatty tissue, lymph glands, vessels, and areolar tissue in the process. Axillary cleaning is important because lymphatic permeation is the all important method of spreading the disease not only locally but also at a distance. This procedure permits the removal of all of the structures including the breast, the pectoralis major and pectoralis minor muscles, pectoral fascia and axillary contents in one mass. The chest wall is cleaned thereby diminishing the liability of malignant cells spreading into the adjacent tissues. Throughout the surgical procedure hot moist tapes are used over all exposed

tissue. This step prevents rapid cooling of the body, aids in hemostasis, prevents overmanipulation of tissue, aids in exposure and in the prevention of shock.

Primary closure with interrupted steel alloy sutures has been used in recent years. Prior to that time interrupted cotton sutures were used. The wound has been closed tightly without drainage. Tension sufficient to produce necrosis beneath the sutures is seldom employed. If skin grafts are needed a thick split skin graft is taken from the anterior thigh. A small incision in the axilla, closed with a single suture, will serve as a drainage area. On the third postoperative day this incision is opened to permit drainage of accumulated serum and blood. Closure in the manner described permits the patient to be ambulatory early, the wound to be kept closed, air to be kept out, the dressing clean, less frequent changes of dressings, control of drainage, and finally the patients like it.

After operation the arm of the affected side is suspended upright by traction on the forearm, the upper arm being kept in 90 degree abduction and the forearm at right angles to the upper arm. Gradual motion and exercise is encouraged from the outset. In 3 or 4 days the traction is removed, and the patient has little or no limitation of motion of the extremity and no postoperative swelling. The patient is out of bed on the fourth day or fifth postoperative day. Within 7 to 10 days the wound is healed, sutures have been removed, drainage has stopped, and the patient is ready for postoperative irradiation.

PATHOLOGY

TABLE V.—PATHOLOGICAL DIAGNOSIS IN 205 CASES OF CARCINOMA OF THE BREAST AS REPORTED BY PATHOLOGISTS

Carcinoma reported	Number
Scirrhus carcinoma.....	111
Infiltrating duct carcinoma.....	31
Adenocarcinoma.....	21
Simplex carcinoma.....	16
Medullary carcinoma.....	9
Papillary cystadenocarcinoma.....	4
Comedo cancer.....	4
Colloid carcinoma.....	3
Solid type carcinoma.....	2
Paget's cancer.....	2
Acute inflammatory carcinoma.....	2

Table V presents a list of the types of breast cancer by name and in the order of frequency as reported by pathologists in the hospitals of this city. It is not a classification. It is realized that two or more of these diagnoses may occur in the same breast. One section may show a scirrhous carcinoma while another may show a duct cell type carcinoma. The microscopic diagnoses were from plugs of tissue made into paraffin sections. There were no whole organ diagnoses.

Some pathologists reported the grade of malignancy and others did not. Consequently, there has been no tabulation of this information. The table shows an overwhelming number of scirrhous carcinomas. This type of growth is the slow growing and radioresistant cancer. The 31 cases of infiltrating duct cancer may be considered in the same category as the scirrhous carcinoma. There were 21 cases of adenocarcinoma. These growths are of relatively low malignancy and remain localized for a long time. Axillary node involvement is exceptional. Grossly the adenocarcinoma is a bulky, soft tumor. There were 9 cases of medullary cancer, which is a rapidly growing tumor and often invades the skin, ulcerates, and appears on the surface as a large, fungating mass. We had 2 cases of acute inflammatory cancer.

One was that of a well developed, well nourished woman of 35 years who had two children. One child was 4 years of age and the other a newborn. In the terminal weeks of her second pregnancy she developed a slight hardness and enlargement of the left breast. After delivery the swelling and hardness persisted. The breast became tender and painful. The pain was generalized and grew progressively more severe. We first saw her 6 weeks after the onset of symptoms and at this time the left breast was enlarged, hard, reddish, and very tender. It was opaque to transilluminated light. There was a hard, round, freely movable gland about 1 centimeter in diameter in the left axilla. The roentgenogram of the chest was negative. She did not nurse the newborn baby. A left radical mastectomy was done with extensive removal of skin tissue and extensive cleaning of axillary and clavicular regions. A large skin graft was taken from the thigh to cover the left breast area. The pathological diagnosis revealed infiltrating duct carcinoma, grade III, with metastasis to regional lymph nodes. Postoperatively, she was given roentgen therapy to the left breast, axillary, and clavicular regions. She was sterilized by the roentgen therapy and supported with testosterone propionate. Six

months after surgery she appeared to be in fair condition. She has maintained her weight and there is no evidence of metastasis but she has had a difficult time with the pain and the discomfort of roentgen therapy. Prognosis is poor in her case. The increased vascularity and cellularity of the mammary gland, the intensified endocrine influence, the rapidity of growth, the diffuseness of the growth, the glandular involvement, the grade of malignancy give us cause for pessimism in the prognosis of this case.

ROENTGEN THERAPY

We have employed postoperative irradiation and irradiation for recurrences or metastatic carcinoma as a routine. In some cases in which the disease was well within the limits of surgical dissection postoperative roentgen therapy was not given. In selective cases we have employed irradiation castration. This phase of therapy is probably most beneficial in cases with metastatic involvement. Irradiation extends the margin of safety and prevents or inhibits recurrences from malignant cells which may have been spilled in the wound or were present in places inaccessible to surgery. The results obtained with roentgen therapy will depend upon the pathological histology, the radiosensitivity of the tumor, the extent of involvement, the bodily build of the patient, clinical course of the disease and other factors. In general, the technique of divided dosage has been used especially when the disease has spread beyond the limits of the involved mammary gland itself. Thus the margin of safety is extended to the parasternal axillary, and clavicular regions.

Irradiation has been initiated within 2 weeks after operation. It has not interfered with healing and has not delayed convalescence. Scirrhous carcinoma is highly radioresistant as are most tumors that are markedly desmoplastic. The highly cellular medullary form may be quite sensitive to irradiation. Adenocarcinoma and duct carcinoma do not respond well. The rapidly growing anaplastic forms respond best, but as they metastasize at an early date they have the worst prognosis. The large amount of fat in the breast is a formidable barrier to irradiation. The outlying islands of tumor cells are very apt to escape unharmed. Microscopic sections of tissue removed at the time of surgery show that the lymph nodes on the anterior surface of the

pectoral muscles are involved in many cases of scirrhus carcinoma at the time of operation. Such nodes are hard to reach with irradiation alone.

Irradiation castration in premenopausal women was employed in selected cases. Irradiation of ovaries has been used to eliminate the ovarian estrogenic function, prevent pregnancy, and the physiological process accompanying pregnancy. This has not been a routine practice because it is felt that the benefits are temporary. Menses often reappear and the ovarian function re-establishes itself. The ordeal is most uncomfortable and it produces many complaints from patients and not a little emotional and nervous upset. Many patients have stated that they would prefer another operation rather than submit to further irradiation. Notwithstanding these apparent disadvantages we have continued with irradiation castration and have not employed surgical castration. In some instances the patients have been supported with testosterone propionate. Massive dosage of 100 milligrams or more daily are required to inhibit estrogen function and give palliative relief. At the present time the cost of this drug in the required dosage is prohibitive to most patients.

FINAL RESULTS

There were no operative deaths and no cases of shock. This fortunate circumstance was favorably influenced by the maintenance of good standards in determining the operability of patients as outlined, by proper pre-operative preparation, by competently administered, suitable anesthesia, by hemostasis, the use of hot tapes during the operative procedure, by the avoidance of shock and by the employment of atraumatic surgery as much as possible. No fluid was administered intravenously during the surgical procedure. In 30 patients operated upon within 3 years there was no metastatic involvement. Two, or 7 per cent, of these died of recurrences of the disease. Thus 93 per cent of those operated upon within the past 3 years are living and well. Of the 60 without metastatic involvement who have been operated upon more than 3 years ago, 49 are living and well. For those without metastatic involvement and who were

TABLE VI.—FINAL RESULTS IN 205 CASES OF CARCINOMA OF THE BREAST

	Without metastasis	With metastasis
Operative deaths.....	0	0
Living and well but operated on less than 3 years ago....	28	31
Total deaths from recurrence of those operated upon less than 3 years ago ..	2	7
Living and well more than 3 years ..	14	11
Living and well more than 4 years ..	9	9
Living and well more than 5 years ..	27	19
Deaths from intercurrent diseases ..	3	4
Total deaths from recurrence of the disease more than 3 years after surgery ..	10	31
Percentage survival of those operated upon less than 3 years ago ..	93.3	81.6
Percentage survival of those operated upon more than 3 years ago ..	83.3	55.7
Percentage survival of those operated upon more than 5 years ago ..	80.1	51.4

operated upon more than 3 years ago the percentage survival rate is 83.3. If operated upon more than 5 years ago the percentage rate is 80.1.

With metastatic involvement the results are less favorable. There were 38 patients with carcinoma of the breast with metastatic glandular involvement who were operated upon within the past 3 years. Seven, or 18.4 per cent, of these have died of recurrences. There were 74 patients with metastatic glandular involvement who were operated upon more than 3 years ago. Thirty-nine of these are still living and well. Of those with metastatic involvement who were operated upon more than 5 years ago 51.4 per cent are living and well. Table VI shows that the results are much better when patients are operated upon before glandular invasion has occurred.

RECURRENCE AND METASTASIS

Sooner or later after carcinoma of the breast has been treated the disease may again manifest itself. Treatment as we have mentioned will retard and delay recurrences and metastases. In 1 case of carcinoma of the breast treated with radical mastectomy the metastasis became clinically evident 12 years later.

One wonders if this was a recurrence, a metastasis, or a new-growth independent of what has gone on before. When metastasis occurs it becomes the duty of the physician to use means at hand to combat the growth, prolong life, give comfort and encourage a cheerful outlook.

Bone, visceral, and skin metastases may occur from any grade of breast cancer. The metastasis is a manifestation of the generalized extension of the disease throughout the body. The extension may have taken place by lymphatic extension, by permeation, by lymphatic emboli, by embolic dissemination and by way of the blood stream. The most frequent osseous structures involved are the vertebrae and pelvic bones and the most frequent visceral involvement are the lungs and abdominal organs. Pain usually is the first clinical warning of the presence of cancerous tissue in bones. The pain is caused by involvement of the periosteum or adjacent nerve trunks with metastasis or surrounding inflammatory reaction. Visceral metastasis to the pulmonary, pleural, and mediastinal structures will manifest itself with pleural effusion, cough and pain, dyspnea and orthopnea. When abdominal organs are involved there usually is an abdominal mass with ascites. In the skin we find carcinomatous dermatitis with skin nodules of various sizes, some of which may ulcerate. Roentgenograms are taken if complaints of pain and other evidence suggest the possibility of metastasis. Irradiation can be applied to structures involved by cancer which are inaccessible to surgery. Palliative measure may include tapping of fluid in serous cavities, irradiation, hormonal therapy, excision of skin nodules, relief from pain, sedation and psychosomatic therapy.

SUMMARY

Routine and frequent examination of the female breast is the key to discovery of much early mammary carcinoma. All breast tumors with the exception of the simple cyst which totally disappears on aspiration should be re-

moved surgically and a pathological diagnosis made.

A lump in the breast was the most frequent indication of carcinoma in our series; 88.3 per cent had this complaint. Over 50 per cent of the patients knowingly possessed a lump in the breast more than 6 months before submitting to treatment. The fourth decade was the most vulnerable to carcinoma of the breast, both as to frequency and metastatic glandular involvement. In 54.6 per cent of the cases the regional lymph glands were involved with metastases. Surgical biopsy and microscopic diagnostic examination were carried out preoperatively in all cases. Routine treatment consisted of radical mastectomy and postoperative irradiation. The surgical technique permitted maximum removal of tissue *en bloc*. Removal was done through a transverse elliptical incision which encircled maximum skin tissue and breast tissue about the tumor. A second incision is made at right angle from the first upward to the shoulder. The pectoralis major and minor muscles were removed, and thorough cleaning of the axilla, clavicular regions and chest wall was done as part of the surgical procedure.

Postoperative irradiation was carried out as a routine. In selected cases preoperative irradiation and irradiation castration have been employed.

The final results show that those operated upon prior to metastatic involvement live longer and the prognosis is much better. In cases without metastasis there was a 93.3 per cent survival rate for those operated upon within 3 years and an 80.1 per cent survival rate for those operated upon more than 5 years ago. Whereas in cases with metastatic involvement the survival rate for those operated upon within 3 years was 81.6 per cent and for those operated upon more than 5 years ago the percentage survival was 51.4 per cent.

Metastases to bone and viscera take place equally well. Once metastasis has occurred the outlook is usually poor and it becomes necessary to use palliative means to keep the patient comfortable and cheerful.

RECONSTRUCTION OF BONY DEFECTS OF THE FACE

With Special Reference to Cancellous Iliac Bone

DOUGLAS W. MACOMBER, M.D., F.A.C.S., Lieutenant Colonel, M.C., A.U.S., Denver, Colorado

DEFINITIVE phases of war surgery have indicated functional and cosmetic restoration of damaged and destroyed bone. A conspicuous portion of such surgery is concerned with facial and cranial structures. Vast numbers of cases, many with aberrations and complications rare or unknown in civil practice, have afforded an unprecedented opportunity to appraise several methods of treatment. In one of the Army's plastic and maxillofacial surgery centers during the past year we have performed approximately 200 operations requiring replacement of bone and restoration of contour in the face and jaws. Adequate data are now at hand for a fair comparison of substances and tissues used and techniques applied. The purpose of this paper is to review our experience with tantalum, acrylic, homogeneous and autogenous cartilage, and bone. Evidence indicates that cancellous iliac bone is the substance of choice in the repair of the majority of such defects, large and small. The chief exceptions are large soft or pulsating cranial defects, which are being so successfully covered by tantalum plates. However, numerous depressed skull fractures and contour defects common about the frontal processes, orbital rims, malar and zygomatic regions are effectively corrected with relatively simple cancellous bone grafts. Results have been uniformly good, even in areas badly crushed, septic until recently, or complicated by foreign bodies.

TANTALUM

Success of neurosurgeons in applying accurately prefabricated metal plates to cranial defects led a predecessor to attempt their use in camouflaging depressions incidental to irreducible malar fractures. Immediate cosmetic effects were fair in several cases, but

septic reactions and displacements demanded their early or ultimate removal in all but 3 cases. To our knowledge, about 1 out of 2 patients was dismissed with the plate in place; in the other cases the operation was redone with bone or cartilage. Not insignificant were patients' complaints of sensations of cold upon exposure during cold weather. Thus, this method of dealing with facial contour defects was abandoned.

ACRYLIC

Observations upon acrylic implants are very limited. The eye department is pleased with results from wedges of the substance in damaged or depressed orbital floors to elevate the globe of the eye. There is a possibility of these bodies eroding into the antrum in case of tissue reaction where bone is missing and much fibrous tissue present. No such instances have occurred, however, and the patients are improved cosmetically and functionally. For the sake of discussion, however, the plastic surgery department contends that all of us would feel more confident in utilization of a viable substance, such as cancellous bone, in precarious locations.

One officer patient presented himself with the lower end of an acrylic implant protruding from his left nostril. It had been inserted overseas to correct a traumatic saddle nose. There was no evidence of sepsis, but the nasal mucosa apparently had undergone a pressure necrosis and given way. Certainly this would not have occurred over viable autogenous tissue.

It may be safe to predict that indication for this means of tissue support will be limited to very few cases.

FASCIA LATA, FAT, AND DE-EPITHELIALIZED SKIN

For small depressions—where protection of underlying structures, rigid support, or strength

From the Department of Plastic Surgery, O'Reilly General Hospital, Springfield, Missouri

Fig. 2. Correction of contour and restoration of orbital rim with cancellous bone. Graft was not wired in place; it was inserted into a pocket against freshened bone of recipient site.

are unimportant—fascia lata serves admirably. One or two strips taken with the fascia stripper may be tucked into the depression through a tiny incision, distributed and modified as requirements indicate. It is found that overcorrection is not necessary, since shrinkage or absorption is negligible.

Apparently fat has been practically abandoned as a free graft. It seems not to be readily vascularized, has low resistance to infection, is prone to absorption and fibrosis. Thus danger of unpleasant immediate complications is great; central portions of large grafts are subject to liquefaction and necrosis; the degree of absorption is unpredictable. Certainly there has been no indication, to our knowledge, for the use of free fat in war surgery.

However, fat as a small attached local rotation or sliding subcutaneous flap has served us well for correction of innumerable small depressions. Penetrating, perforating, and lacerating wounds of the face, with varying amounts of tissue lost, have resulted in every manner of superficial defect. Grooves, furrows, pits and depressions catch lights and shadows in such a way as to accentuate their importance, especially to sensitive patients. In depressions involving the beard area, the chief complaint is returned hairs and interference with shaving.

Practically anywhere on the face it is possible to draw a pedicle of adjacent attached fat into a small depression without noticeably or objectionably altering contour of the area.

It may be preferable to use figure-8 or other removable stitches to hold the pedicle in place until it is established, rather than to chance irritation or foreign body reaction to buried suture material.

Previous literature has recommended and evinced a moderate amount of enthusiasm for skin minus its epithelium for filling shallow depressions or for strengthening so called weak integument. It is my impression that it cannot do anything that fascia lata or other tissue cannot do better and with less danger of sepsis and absorption. One cannot be certain that all secreting and excreting elements of the skin have been removed. Tissues that have survived the inestimable crushing and concussion of a war injury may be less able to cope with factors which complicate or retard healing than are tissues that have endured less violent trauma. We have had no occasion to use this technique in any of the depressed areas and have dismissed it as impractical, at least in a series of this type.

CARTILAGE

Obviously cartilage is established as a tissue of choice in many defects, particularly nasal depressions and ear reconstructions. The only debatable phase of the question seems to be whether the cartilage shall be homogenous or autogenous. Advocates of the former contend that it is preferable wherever cartilage is indi-

Fig. 4. Lower orbital rim, malar bone, and zygomatic arch have been replaced by one large block and several smaller fragments of cancellous bone.

cated, chiefly because it saves the patient an uncomfortable incision over the costochondral region and because it is less apt to twist or curl. Other considerations being at least equal, we have preferred preserved cartilage because of its saving us the additional surgery to procure autogenous substance. It may be stated conservatively that utilization of the preserved tissue saved us at least 70 operations during 1945. Considering the fact that 3500 operations were carried out in the plastic surgery department of a single hospital during this period, we grant that such a time saving consideration enables us to perform an increased total number of operations. We have buried many plates of preserved cartilage beneath the skin about burned and partially destroyed ears and placed split skin grafts behind them a few weeks later with practically no disappointments. Even in instances in which scar epithelium looked as though it might break down if undercut, the skin has survived and improved as it has contributed to the reconstruction of an ear. These ears appear to be substantial and so far as we know the cartilage is showing no tendency to be absorbed. I recall 2 instances of cellulitis which subsided without loss of the cartilage and 2 instances of gross infection, mentioned later, in which it was expelled or removed. It will be interesting to note whether any of these patients suffer absorption or expulsion of the graft in the future. After all, preserved cartilage is nothing more than a benign foreign body. A previous generation of surgeons favored ivory—and some of it did its work quite well for years. In 1943 in the European theater I removed an ivory implant, from one of the older Air Corps officers, that had been placed in his traumatic saddle nose following an airplane crash in World War I. It had become displaced and had festered periodically during the past 3 years. Dorsal and columellar elements were ingeniously dovetailed together like an intricate Chinese puzzle. There was no evidence that time had in any way impaired the material. After a few weeks this nose was successfully built up with a cancellous iliac bone graft.

Since the type of work done in this military hospital is rarely followed by a death, we have

Fig. 5, left. Depressed fracture of frontal bone.

Fig. 6. Result from insertion of one large and several smaller pieces of cancellous bone. Note incision above hairline.

had no opportunity to collect any cartilage from the department of clinical pathology. Thus we came to depend upon other institutions to procure for us the material from suitable donors under aseptic precautions. We cultured the material, transferred it to new merthiolate-saline solution and refrigerated it. Repeated cultures were made on any specimens kept over 2 weeks; they were discarded if other than "no growth." Despite these precautions we had 4 cases of infection from one batch of cartilage in the only 4 patients in whom it was used. Drainage from each of 2 ear grafts and 2 nose grafts gave a culture of hemolytic *Staphylococcus albus*. The ear grafts were lost but the nose grafts retained, with some absorption in one and no tangible change in the other. We have not used any preserved cartilage since this experience, and probably will not unless a more dependable source becomes available to us. For small ear cartilage grafts, we take some from the opposite concha in unilateral cases. In instances requiring larger grafts we are making the costochondral incision. For supporting substance elsewhere than the ear, we prefer cancellous bone in most cases. Thus the number of rib cartilage incisions is not a burden to us or to the patients at this time.

CANCELLOUS BONE

Various comments in the above sections indicate the chief message conveyed in this paper—our unqualified satisfaction with cancellous iliac bone. During 1945, 117 iliac bone

Fig. 8. X-ray appearance of mandible graft, clinically firm at 7 weeks.

grafts have been used in facial and jaw defects operated upon by the plastic and maxillofacial department in this one Army specialty center. They have been used in defects which have undergone every possible complication which would make them poor risk areas. Many were the result of severe lacerations or crushing injuries; others communicated with septic sinuses and oral cavities; some housed foreign bodies and sequestra; in several previous attempts had been made at repair with nonvital substances such as vitallium, acrylic, or preserved cartilage; a few were defects which had been abscessed or involved in an area of osteomyelitis or cellulitis. Former arbitrary waiting periods of, say, 5 months between septic or potentially septic conditions

and performance of bone grafts have been ignored. We have merely waited, as a rule, from 3 to 5 weeks after cessation of drainage or subsidence of other signs of sepsis. Penicillin, 25,000 to 50,000 units every 3 hours, has been given routinely for several days post-operatively in all cases except those considered in no way potentially septic. It is granted that this fortification against possible septic complications has encouraged our boldness in proceeding early.

There have been no regrets and no graft has been lost. In 1 instance a small piece of thin cortical bone, which had been left on the graft, separated and had to be removed as a sequestrum. Several patients had local swelling and serosanguineous fluid was aspirated one or

Fig. 10. High power photomicrograph. In this section is shown the new bone and cortex formation at the periphery.

more times from about the bone. Two patients have had cellulitis in overlying skin; with continued penicillin systemically and wet packs locally, it has soon subsided. In no case has the bone graft appeared to be threatened. Union and consolidation occur early and clinical firmness usually is present during and after the third week.

Certain technical considerations which conserve time at the operating table and contribute to uncomplicated healing are worthy of notation: General anesthesia is desirable, if not mandatory, pentothal being used in operations which can be done in approximately an hour and intratracheal gas-oxygen-ether for the longer ones. However, consumption of the anesthetic agent is minimized and gratifying hemostasis attained by injecting both donor and recipient sites with 1 per cent novocain containing 7 to 10 minims of 1:1000 adrenalin per ounce. An incision about 4 inches long parallel to, and just below, the right iliac crest is made to the bone. A wide sharp chisel quickly unroofs the ilium and turns its outer table down like a trap door. The desired amount of bone is removed consisting, if a large amount is taken, of one large block and a few small ones. If the graft is to be large and will require rigidity or strength, as for a jaw, it is well to leave all or part of a thin layer of cortex on one side. Otherwise it may break during its shaping and fixation or early in the convalescence before new bone formation solidifies its structure. An assistant proceeds with closure of the donor area in layers, leaving a Penrose drain for 24 hours. Soft voluminous pressure dressings held in place with wide circumferential stockinette bandages permit a tolerably comfortable postoperative period. Patients state that the "hip was uncomfortable for 7 or 8 days"; most become ambulatory voluntarily at the end of that time. At the recipient site it is commonly possible to excise or reopen an old scar line; otherwise an incision is made favorably situated in the direction of Langer's lines. A pocket is made for the graft, and the bone is freshened at one or more places for contact. Tantalum wire is used for fixation of some of the larger grafts, chiefly those of the mandible and the larger ones in the malar region. In the majority of

other depressions—as orbital rim, forehead, or nose—the recipient pocket contains the bone firmly and no special fixation is indicated. After the main block is in place, dead space and contour irregularities are occupied by chips of the residual cancellous material. It is readily broken or cut with stout knife or scissors, then laid or pressed into place until contour and bulk are correct. Simple closure without drainage and soft pressure dressings maintain the bone safely "home." Usually firmness is noticed at the first change of dressings from 3 to 5 days later. At that time, penicillin is withdrawn if there is no evidence of a septic reaction.

There can be no doubt that cancellous bone is rapidly vascularized, probably as rapidly as a free skin graft. Otherwise it would not "take" so dependably in areas badly traumatized and formerly or potentially septic. It is actively osteogenic and rapid new bone formation is grossly indicated by the early firm attachment and substantial feel.

A left-over block of the material was hoarded in a patient's subcutaneous abdominal fat. It was removed for study at the end of 7 weeks. Our pathologist (Major G. D. Ayer, Jr.) described the gross specimen and his comment, in part, upon the microscopic picture is as follows: "Nine sections comprise gross serial cross sections taken in the long axis of the specimen. In most locations there is incomplete formation of cortex beneath the moderately dense connective tissue investment."

On a previous occasion, in the case of the Air Corps officer whose ivory graft for saddle nose was replaced by a cancellous iliac bone graft, a spindle-shaped piece of the material was likewise hoarded. Several months later an x-ray flat plate of the abdominal wall showed the specimen with a dense cortex and less dense medullary core.

SUMMARY

The problem of restoring facial bones functionally and of correcting contour defects cosmetically has been surveyed in a general way. No attempt has been made to describe any one method in exhaustive detail. However, the use of various materials, both inorganic

and organic, homogenous and autogenous, has been discussed entirely from personal observation and experience in an unusually large series of cases. Results from foreign substances have been consistently bad; utilization of homogenous human substance brings in added possibilities of contamination, incompatibility and tissue reaction; autogenous tissue, other than bone, in some cases has been inadequate, undependable, or unpredictable. Cancellous bone has served well, often in areas that had been badly traumatized or septic, with success and gratifying end-results.

Several exemplary cases are mentioned, some with "before and after" pictures illustrating corrections which show no tendency to become distorted, absorbed, or otherwise modified by time. Since the graft is composed of living and established tissue, there is little or no danger of ultimate disappointment.

Gross observation and microscopic study has been made upon hoarded specimens to demonstrate that these grafts become rapidly vascularized, are osteogenic, and develop their own cortex. Their survival does not depend upon bony contact.

CONCLUSIONS

1. For correction of contour defects and bony losses in facial structures, several substances are available. It is my opinion that all of the foreign substances should be abandoned.

2. Homogenous preserved cartilage has its useful place, particularly in replacing lost ear cartilage and in other relatively minor defects where strength or support is not a significant requirement. It should be taken from a proved "clean" donor under aseptic conditions, preserved in antiseptic solution changed occasionally, refrigerated, and cultured every 2 or 3 weeks.

3. Fat is practically useless except as a local attached subcutaneous pedicle for small depressions.

4. Fascia lata is sometimes preferable for shallow depressions and probably serves more safely and dependably than de-epithelialized skin.

5. Iliac cancellous bone is a singularly dependable, utilitarian, safe, and satisfactory tissue for correction of the types of defects that have been discussed.

gauze to prevent aspiration of material into the lower air passages. In cases of this kind because of the usually marked extent of disease it is our belief that a radical neck dissection should accompany the resection of the mandible whenever the general condition of the patient will allow, and this will apply to most patients under 60 years of age.

On these occasions the dissection is begun just above the clavicle with division of the sternomastoid muscle and the internal jugular vein. When the level of the external carotid artery is reached, this vessel is ligated in continuity distal to its superior thyroid and laryngeal branch. Pads are placed in the lower part of the wound, and attention is momentarily diverted to the oral cavity. Here the mucosa of the floor of the mouth is incised as far as the subjacent lesion requires, either the scalpel or the endotherm knife being used. On introducing a finger into this incision one finds a ready plane of cleavage between the mylohyoid muscle and the muscles of the tongue. The lingual nerve is appreciated as a band and some care must be exercised to prevent its avulsion. A similar incision is made through the mucosa of the gingivobuccal gutter, and by blunt finger dissection this is easily deepened into the subcutaneous fat of the cheek as far as is indicated, usually to the inferior border of the mandible. Very little bleeding results if the facial veins are not torn. These two incisions are lightly packed with moist gauze. The upper cervical skin flap is next developed superficial to the platysma muscle whereupon communication is established with the lateral mouth plane. All skin attached to the mass is widely sacrificed. At the spot chosen for sectioning the mandible, a Gigli saw is passed around it and the bone is severed. The contents of both submental spaces are dissected to the lateral border of the ipsilateral anterior digastric muscle belly; the portion of mandible to be removed is retracted upward and laterally, and the mylohyoid muscle is cut free of the hyoid bone. Thus the node mass is left entirely undisturbed, bounded superiorly by the mandible, externally by the platysma muscle, and deeply by the mylohyoid muscle. From this point one may proceed to free the man-

dible from its muscular and ligamentous attachments and to complete the upper posterior portion of the neck dissection in the usual manner. The mucosal edges of the oral cavity wound are apposed by means of a Connell type of stitch reinforced with a row of interrupted sutures. After mucosal closure has been completed the entire neck wound is lavaged with liberal amounts of physiologic saline. Several small Penrose drains are appropriately placed and the wound is closed.

Whenever considerations relative to the patient's physiologic reserve indicate that so extensive a procedure may not be tolerated, attention is paid to the known disease first. The external carotid artery is ligated, the intraoral incisions are developed, the upper skin flap is formed, and coincident removal of the jaw and submaxillary contents is continued. Before the specimen is detached laterally, however, an appraisal of the situation may again be made with completion of the neck dissection from above downward if circumstances latterly seem to warrant it. Though one is naturally desirous of doing wide *en bloc*, dissection of all suspected tissues, the initial accomplishment of a suprahyoid dissection and mandible resection followed at a later date by completion of the neck dissection is entirely feasible and is certainly an occasionally legitimate compromise in poor risk patients. Whenever extensive disease is also present in the primary tumor site, this is widely excised (lip, buccal mucosa or gingiva) in continuity with the jaw and node. It will sometimes be impossible to accomplish an immediate restoration of the part. Resultant defects are left for subsequent repair and anticipation of them should in no way influence the primary consideration, namely wide removal of the tumor mass.

In sectioning the mandible the functional and cosmetic results are directly proportional to the amount of chin which can be spared. When the anterior portion of the mandible must be sacrificed because of tumor fixation bilaterally, the typical "Andy Gump" deformity results. When bilateral submaxillary metastases are present which though firmly attached to the mandible on one side are only moderately fixed over a small area on the

other, it has been our practice to resect the mandible with the nodes on the side of the marked adherence only. On the opposite side several millimeters thickness of the inferior border of the mandible only is removed, the object being to spare the anterior mandible whenever this can be accomplished without undue risk. Detachment of the anterior tongue supports (genioglossus muscles) permits that structure to be drawn posteriorly and downward filling the hypopharynx interfering with the airway, sometimes for a prolonged period. Speech and proper deglutition are permanently impaired. Drooling is very apt to occur. In accomplishing lateral mandibular resections it is therefore important to preserve as much of the anterior jaw as possible. It has been our practice to remove less mandible in the absence of roentgenographic evidence of involvement than when such involvement was demonstrated to be present. Usually the bone is cut 0.5 to 1.0 centimeter anterior to the attachment of the mass when roentgenologic signs of bone destruction are absent. Since the involvement is usually along the inferior border of the mandible we have practiced cutting the mandible obliquely so as to preserve a 1.5 by 2.5 centimeters longer superior than inferior border. If the bone is invaded, however, one has little knowledge of how far extension in the medullary canal may continue, and if the bone involvement is extensive, it seems likely that the safest point for anterior division of the jaw would be through the symphysis. After the mandible is freed of its muscular attachments, it is then customary to disarticulate it. In order to avoid troublesome pericapsular bleeding about the joint the condyloid process may be severed with a rib cutter, however. In the absence of advanced bone invasion this should result in no harm. On the contrary a large fragment of ascending ramus left behind will not only increase the chances of recurrence but will invariably be drawn upward and inward by uncompensated temporal and pterygoid muscle pull and will produce severe discomfort on mastication.

Catgut of suitable size is used throughout except for skin closure which is accomplished with silk or cotton. Buried nonabsorbable

suture material, though it does no harm has produced late granulomas which are extremely worrisome to the patient who is usually alert for signs of recurrence.

The actual cautery has not been used in any of the procedures since the need for sealing lymphatics is highly theoretical. Should the lymphatics at the point of transection be permeated by disease, it is highly unlikely that the cautery would be any more effective than the scalpel in preventing recurrence. The cautery presents the disadvantages of so altering the tissues as to interfere with accurate palpation which we consider to be essential to accurate removal, and also interferes with primary healing. Careful local hemostasis aided by preliminary arterial ligation for the rigid maintenance of exposure and careful palpation with wide excision are essential, we believe, if one is to safeguard against transecting cancerous tissue.

Where trismus is present preoperatively, tracheotomy is done preliminarily and the anesthetic is administered by this route. Excepting such instances, however, the tracheotomy is not done until the resection has been completed and it is then accomplished routinely. The patient is informed before the operation that he will be unable to speak for several days following it and that the tracheal opening will be permitted to close spontaneously when all swelling in his throat has subsided. Tracheotomy tubes require considerable nursing care in keeping them clean and free of mucus. Increasing the humidity of the room by means of a steam kettle will diminish tracheobronchial secretion and crusting of mucus. At least one transfusion, and usually several are administered during the operation. These are given to replace blood lost and as prophylaxis against shock. Accordingly transfusion is begun shortly before or at about the time the skin incision is made. Hot saline mouth irrigations are started on the day after operation to cleanse the intraoral suture line and are repeated at hourly intervals during the day until the mouth is well healed. If the patient evidences no nausea, a small caliber Levine tube is passed into the stomach on the first postoperative day, and tube feedings are begun in small amounts of 100 to 150 cubic

centimeters five or six times daily, increasing the amount each day to meet bodily requirements. At the first complaint of nausea the gastric contents are aspirated, the tube is removed, and the feedings are temporarily discontinued. A patient with a tracheotomy tube is unable to clear his airway with the explosiveness that the functioning glottis permits and therefore all possibility of aspirating food must be strictly avoided. The patient is urged to get out of bed by the third or fourth postoperative day. Prior to that time he generally feels too ill to do so.

CASE 1. No. 4109. Patient a white male, aged 67 years, was admitted May 15, 1942. An unidentified tumor was removed from the mucosa of the right cheek with cautery 8 months before admission. He had had a lesion of the left lower lip treated similarly 7 years previously. For 3 months prior to hospital entry he had noted progressive enlargement of a mass in the right submaxillary space recently productive of constant pain in the jaw.

Examination revealed an old scar on the left vermilion border of the lower lip and another on the right buccal mucosa just posterior to the commissure of the mouth. The entire right submaxillary space was filled with a large mass approximately spherical and solidly fixed to the mandible. The overlying skin was thin, tense, and discolored indicating impending breakdown. There were no other palpably enlarged lymph nodes. An aspiration biopsy specimen was reported epidermoid carcinoma. Roentgenograms of the mandible showed no evidence of bone invasion and those of the chest gave no evidence of metastatic carcinoma.

Accordingly on May 29, 1942, an *en bloc* resection of the right mandible and contents of the right neck (excepting the posterior triangle), was done and the postoperative course was uneventful. The laboratory examination of the specimen revealed involvement of the large submaxillary node only with extension out into the surrounding soft tissues. There was bone invasion in one area and wide periosteal involvement.

A series of subsequent events then occurred in the following order:

August 5, 1942, a recurrence was noted in the soft tissue at the posterior extremity of the upper incision. This was widely excised.

October 16, 1942, two nodules were noted midway down the cervical border of the trapezius muscle. These were excised along with all the skin of the neck and the contents of the posterior triangle and the defect was covered with a large dermatome split thickness graft.

August 23, 1946, no further evidence of disease has been noted to date.

CASE 2. No. 4302. A white male, aged 69 years, was admitted July 9, 1942. Patient stated that a

rapidly progressing lesion had been present on the lower lip for only 1 year.

On examination the entire lower lip including both commissures of the mouth, was involved by a fungating mass firmly attached to the mandible. Conglomerate nodes were present in both of the submental and the submaxillary spaces and were also adherent to the mandible. Biopsy revealed an epidermoid carcinoma, grade 1. Roentgenograms revealed no evidence of actual mandibular destruction or pulmonary metastases.

On July 14, 1942, an *en bloc* resection of the lower lip, the anterior portion of the right horizontal ramus of the mandible, and all of the left horizontal ramus of the mandible was combined with a left total neck dissection. On pathological examination a tumor was found growing diffusely in the submaxillary space but none of the jugular nodes was involved. The postoperative course was uncomplicated.

On August 14, 1942, a left supraomohyoid neck dissection was done. Capsular invasion of the involved lymph nodes was noted microscopically with wide periosteal involvement. There was no demonstrable invasion of the jaw. Convalescence occurred without incident.

During follow-up a recurrence was noted adjacent to the anterior end of the left mandible. This was excised January 29, 1943.

Plastic repair of the face defect had been begun August 5, 1942, and was finally completed September 3, 1943; a skin tube swung from the chest wall was used with a satisfactory cosmetic and functional result. The patient remained free of any evidence of disease, but expired rather suddenly at home of pneumonia on April 30, 1945.

CASE 3. No. 5471, white male, aged 76 years, was admitted July 29, 1943. One year before he had had a "cancer" removed from lower lip. A mass had been noted below the left jaw 2 months prior to admission. A small defect was present on the vermilion border of the left side of the lower lip without evidence of residual disease. An ulcerating mass filled the left submaxillary region and was densely adherent to the mandible. There were no other palpably enlarged nodes. A biopsy revealed grade 1 epidermoid cancer. Roentgenograms showed an area of bone destruction along the inferior border of the left horizontal ramus of the mandible. The lungs appeared to contain no metastases.

A resection of the left mandible was combined with a supraomohyoid neck dissection on August 7, 1943. A tracheotomy was not done at the time of resection. However, about 5 hours later the patient developed marked stridor and a tracheotomy was done on the ward. The postoperative course thereafter was uncomplicated.

On examination of the operative specimen, disease was found only in the large ulcerated submaxillary node. The clinically noted bone invasion was confirmed and extensive periosteal involvement was present. The patient remained well until April 14, 1944, at which time a metastatic node was found in

the right (opposite) submaxillary space. It measured 2.5 centimeters in diameter when first seen and was moderately adherent to the inferior border of the right mandible. A supraomohyoid neck dissection was done and at the point of attachment of the node to the mandible several millimeters' thickness of bone was also removed.

The postoperative course was uneventful and the patient remains well 2 years and 6 months later.

CASE 4. No. 5725. A white female, aged 83 years, was admitted to the hospital October 13, 1943. She had developed a lesion at the left corner of the mouth 18 months prior to admission, and had been treated with radium. At the time of treatment to the primary lesion a small lump was already noted in the left submaxillary space. A few x-ray treatments had been given without apparent effect. On admission a scar without evidence of persistent disease was present adjacent to the left commissure of the mouth on the upper lip. The left submaxillary space and upper neck were filled by a large, deeply cratered mass fixed to the mandible and deeper neck structures and measuring 8 centimeters in diameter. The common and internal carotid arteries were palpably free of the mass. There was marked trismus and pain in the jaw. Biopsy of the crater was reported epidermoid cancer, grade 1. A roentgenogram of the chest revealed no metastatic foci in the lungs. Films of the mandible showed erosion of the inferior border of the left horizontal ramus by the tumor. Initial impression was that symptomatic treatment alone was indicated; however, the patient pled so fervently for removal of the tumor that it was finally decided to attempt this.

On October 25, 1943, a resection of the left mandible and node dissection was done. It had been intended to confine the dissection to the upper neck; however, small but grossly involved nodes were noted along the course of the internal jugular vein. The patient had been doing very well up to this point and it was decided to complete the neck dissection with removal of the sternomastoid muscle and internal jugular vein. During this part of the procedure the endotracheal tube slipped above the glottis, and either as a result of cord spasm or laryngeal edema the airway was shut off completely and marked cyanosis was noted. A tracheotomy was hastily done but a sharp though transient drop in blood pressure occurred. The patient never fully regained consciousness and expired about 20 hours after operation. An autopsy (exclusive of a brain examination) failed to reveal any decisive cause of death. Examination of the operative specimen revealed metastatic involvement of the preauricular, submaxillary, and upper jugular lymph nodes.

CASE 5. No. 6689. A white male, aged 36 years, was admitted to the hospital August 23, 1944. He had noted a pea-sized lesion of the vermilion border of the lower lip 2 years prior to admission. This tumor was treated with roentgen therapy x year later and rapidly disappeared. A mass was noted in the right submaxillary region 8 months before ad-

mission with subsequent marked increase in size. On examination a small scar was noted to the right of the midline of the lower lip without evidence of persistent disease. The right submaxillary space was filled by a mass measuring 6 centimeters in its greatest diameter, solidly fixed to the horizontal ramus of the mandible. The overlying skin was thin, discolored and adherent. No other nodes were palpable. Routine laboratory studies were unremarkable and an x-ray film of the chest failed to reveal any evidence of pulmonary metastases. Roentgenograms of the mandible revealed no architectural changes. An aspiration biopsy of the mass was reported "epidermoid carcinoma." On September 1, 1944, a right radical neck dissection with resection of the right mandible and tracheotomy was performed without untoward event. The pathologist reported epidermoid carcinoma, grade 2, metastatic only to the single large submaxillary node though 77 negative nodes were found in the specimen. There was extensive periosteal involvement. The patient's postoperative course was entirely satisfactory, and he was discharged from the hospital September 17, 1944, his sixteenth postoperative day. He was last seen in follow-up on October 11, 1946, and presented no evidence of recurrent or metastatic disease.

CASE 6. No. 7082. A white male, aged 71 years, was admitted to the hospital December 13, 1944. Approximately 7 months prior to entry he had noted a blister of the lower lip which had progressed rapidly. He received roentgen therapy without apparent effect. Four months before admission a mass had appeared in the left submaxillary area. This had increased in size eventually ulcerating through the skin. On admission the entire lower lip, excepting the base, was involved by an ulcerating mass measuring 7 centimeters in transverse diameter extending into the left buccal commissure. A left submaxillary mass measuring 4 centimeters in diameter was present. This was firmly attached to the mandible and had ulcerated through the overlying skin. No other adenopathy was present. Biopsy specimen revealed epidermoid carcinoma grade 2. X-ray examination revealed no evidence of mandibular destruction or pulmonary metastasis. An excision of the lower lip was carried out on December 19, 1944. On January 15, 1945 a left mandibular resection and a suprahyoid neck dissection were done. Though the procedure presented no unusual difficulty, the patient's blood pressure dropped alarmingly on several occasions requiring rapid administration of blood. As a result of this, pulmonary edema supervened and a large amount of pink froth was suctioned off from the trachea. Rapid digitalization was accomplished and was followed by an uneventful course.

On February 25, 1945 a node was noticed in each subdiaphragmatic area, and on aspiration biopsy these were found to contain epidermoid carcinoma. On March 1, 1945, a radical neck dissection was completed on the left. Two weeks later, March 16, 1945, a right radical neck dissection was done. Marked congestion and edema of the head structures lasting

more than a week followed removal of the second internal jugular vein but produced no other untoward effects.

A total of 10 nodes were found to contain disease in the several dissections. None of these was from the lower neck. There was extensive involvement of the periosteum but no invasion of the cortex of the left horizontal ramus of the mandible. The patient is now in the process of having a lower lip constructed, and 19 months following the last dissection remains free from evidence of disease.

CASE 7. No. 6971. A white male, aged 72 years, was admitted November 13, 1944. A lesion of the lower lip had been present no more than 1 year (history felt to be very unreliable). No previous treatment. Examination revealed a bulky foul lesion involving the entire lower lip fixed to the mandible and extending well into the substance of the left cheek. Bilateral extensive submaxillary adenopathy also fixed to the mandible and ulcerated through the skin on the right was present. Pathological diagnosis, epidermoid carcinoma, grade 1. Some erosion of the inferior border of the right horizontal ramus of the mandible was noted on x-ray examination. There was no roentgenologic evidence of pulmonary metastasis. The patient was given a preliminary course of anti-inflammatory x-ray therapy and on December 20, 1944, an *en bloc* removal of the lower lip, a portion of the left cheek and both horizontal mandibular rami was combined with a bilateral suprahyoid neck dissection. The laboratory reported involvement of 9 of 40 nodes found on the right and 4 or 5 found on the left. Node capsular invasion was present generally. A skin tube was begun on the chest wall for eventual repair of the defect, and the patient was discharged from the hospital January 24, 1945. He was readmitted March 14, 1945, with nodes in both jugulodigastric areas.

On March 29, 1945 a total neck dissection was completed on the right with removal of the internal jugular vein. Minimal lobular pneumonitis complicated the postoperative course but responded well to penicillin therapy. Seven of 27 nodes found were involved by metastatic disease. On April 18, 1945, a total left neck dissection was completed without untoward incident. The left internal jugular vein was also removed. Two of thirty-three nodes were involved making the astounding total of twenty-two involved nodes out of a total of 75 found in both sides of the neck.

Apart from marked edema of the conjunctiva, face, tongue and larynx incident to removal of the second jugular, all went well and the patient was discharged from the hospital improving on May 7, 1945, without any further evidence of disease. On May 13, 1945, the patient died suddenly of causes unknown.

CASE 8. No. 7245. A white male, aged 61 years, was admitted to the hospital February 19, 1945. A progressively enlarging ulceration of the left buccal mucosa had been noted for 5 years. No treatment had ever been applied. Six months previous to ad-

mission a mass had appeared below the left mandible. At the time of admission a large exophytic lesion of the left buccal mucosa measuring 6 centimeters in diameter was found. It extended from the oral commissure to the angle of the mandible and from the upper to the lower gingiva. It had penetrated the full thickness of the cheek ulcerating through the skin in one area. The left submaxillary space was occupied by a bulky mass to centimeters in greatest diameter and fixed to the mandible. Ulceration through the thinned out skin overlying the node mass appeared imminent. There was no other palpable lymphadenopathy in either side of the neck. Biopsy was reported epidermoid carcinoma, grade 1. Roentgenograms revealed erosion of the posterior alveolar aspect of the mandible. There was no evidence of pulmonary metastases.

On February 23, 1945 section of the left cheek and left mandible was combined with a left radical neck dissection. Pathological examination of the specimen revealed a well differentiated epidermoid carcinoma with well marked locally invasive properties which had metastasized rather widely to four cervical nodes, two of these being in the jugular chain. There was no invasion of the mandible noted. The postoperative course was entirely uneventful.

Clinic follow-up was unremarkable until November 11, 1945, at which time a swelling was noted in the left temporozygomatic region and a centimeter mass appeared just beneath the mastoid. Aspiration biopsy specimens from both areas showed epidermoid carcinoma. This recurrence was considered to be beyond the scope of surgical removal and a course of roentgen therapy was instituted. Died May 12, 1946.

CASE 9. No. 7328. A white male, aged 69 years, was admitted to the hospital March 19, 1945.

In 1938 a diagnosis of "cancer of the left tonsil" was made and the patient was given a course of roentgen therapy, with complete disappearance of the tonsillar mass. In 1939 a "lump" appeared superficial to the angle of the left lower jaw. This was treated with x-ray in 1940, with temporary regression. Later increase in size resulted in a second series of roentgen treatments in 1943, followed by no perceptible diminution in size. During the year prior to admission the mass on the mandible had again begun to enlarge. On examination no trace of a primary tumor remained anywhere in the oral cavity or pharynx. Overlying the angle of the left mandible and fixed to it was a rounded mass 4 centimeters in diameter. The adjacent skin was attached to the mass and showed moderate secondary epithelial changes as evidenced by complete epilation. There was no other palpable adenopathy present. An aspiration biopsy of the mass revealed "epidermoid carcinoma." Roentgenograms showed erosion of the mandible beneath the tumor. There was no evidence of pulmonary metastases.

On March 3, 1945, the left mandible was resected in conjunction with a left total neck dissection.

Fig. 1. Case 1. Metastases from healed lesion of the right buccal mucosa before combined jaw resection neck dissection and following dermatome graft of the entire one side of the neck for postoperative recurrences. The outline of the left carotid vessels is easily seen.

Careful pathological examination of the specimen failed to reveal any other involved nodes other than that represented by the mass at the crossing of the facial vessels. There was mandibular invasion present. The postoperative course was unremarkable except for poor healing in the area showing irradiation changes with subsequent formation of a small salivary fistula.

The patient has remained well for a period of 18 months and is at present in the process of having the salivary fistula repaired.

CASE 10. No. 7358. A white male, aged 56 years, was admitted to the hospital March 27, 1945.

In January, 1944, a small tumor of the left side of the vermillion border of the lower lip had been treated with radium with good result. In August, 1944 (7 months before admission), "lumps" were first noted in the left submaxillary area. On examination a small scar was present at the site of the original primary growth with no evidence of persistent disease. A large mass was present, filling the entire left upper neck; it was fixed to the horizontal ramus of the mandible, to the deeper structures of the neck in the region of the hyoid bone and had ulcerated through the skin. It measured 8 centimeters in its greatest diameter. There were no other palpably enlarged nodes. Roentgenograms of the mandible revealed no evidence of bone invasion nor did those of the chest show any metastatic involvement. An examination of aspiration biopsy specimen from the mass revealed "epidermoid carcinoma." On April 2, 1945, a resection of the left mandible and left total neck dissection was done. The left wing of the hyoid bone and small musculature in that region were also removed down to the mucosa of the pharynx. Due to unusual vascularity four transfusions were given in the operating room. The patient's condition remained stable until all return through the left internal jugular system had been severed at which time he developed irregular stertorous respirations and a very rapid pulse of very variable strength. A spinal manometer attached to

Fig. 2. Case 8. Showing ulceration of a carcinoma of the buccal mucosa through the skin of the lip with impending ulceration of the nodes through the skin of the neck. The large buccal lesion is seen in the upper right portion of the specimen.

Fig. 3. Cases 11 and 12. Extensive paramandibular metastasis with oral fistulas secondary to carcinoma of the lower lip. The resulting defects are left for subsequent reconstruction accomplished with tube grafts.

Fig. 4. Case 3. Large submaxillary mass secondary to a small beaded carcinoma of the lower lip. Invasion of the mandible is visible on the roentgenogram and the photomicrograph. The necessary wide sacrifice of soft tissue and jaw anteriorly somewhat diminishes the satisfactoriness of the final cosmetic result.

a previously placed needle in the third lumbar interspace (in conjunction with another study) registered a cerebrospinal fluid pressure of 750 millimeters of water which was still rising. After 150 cubic centimeters of spinal fluid had been removed, vital signs promptly returned to normal and the cerebrospinal fluid pressure dropped to 150 millimeters of water. The first two postoperative days were unremarkable and on the third day a Levine tube was inserted for feedings. An absence of a gag reflex was noted during its passage. Vomiting occurred about one-half hour after each feeding and the feedings were discontinued. Aspiration pneumonia supervened, however, and progressed, with death occurring on the seventh postoperative day.

The pathological report on the operative specimen revealed epidermoid cancer present in 2 of 77 nodes found, with a tumor thrombus present in the internal jugular vein. At autopsy extensive necrotizing pneumonitis was found. In addition marked dilatation of the veins overlying the left cerebral

hemisphere and numerous thrombi in the left subdural veins were noted.

CASE 11. No. 7493. A white female, aged 38 years, was admitted to the hospital May 11, 1945. She had developed a sore on the lower lip 10 months before admission. She had been treated with "black paste" and the growth disappeared. One month prior to paste treatment and 8 months before admission patient noted nodules in substance of left cheek and below left jaw. On examination a small scarred defect was present on the vermillion border of the left side of the lower lip indicating the site of the original primary tumor. Just lateral to the left commissure of the mouth and extending well into the substance of the left cheek was a hard indurated mass with ulceration through the skin and buccal mucosa producing a through-and-through fistula. The left submaxillary space was filled by a hard mass firmly attached to the mandible with fistulas into the floor of the mouth. In the right submaxillary space was a solitary 2 centimeter node attached to, but slightly movable on, the horizontal ramus of the mandible. The pathological report was, epidermoid carcinoma, ungraded. Roentgen films of the mandible showed no bone destruction and those of the chest were negative for evidence of bone metastasis.

On May 16, 1945 a wide resection of the left cheek and left mandible was combined with a left radical neck dissection. The pathologist reported that there were no involved nodes below the submaxillary group. There was wide periosteal involvement but no demonstrable bone invasion. The postoperative course was unremarkable.

On June 13, 1945, a right radical neck dissection was accomplished with removal of the second internal jugular vein. Only one node of 55 was found to be involved. The patient is now in process of plastic reconstruction and when last seen September 1, 1946, presented no evidence of disease.

CASE 12. No. 1098. A white male, aged 28 years, was admitted to the hospital June 4, 1945. A lesion of right lower lip of 4 years' duration had been treated with roentgen therapy in January, 1944. Eight months later right submaxillary masses developed. On admission patient presented a small scar on the lower lip. The right submaxillary and both submental areas were filled with a foul ulcerated mass fixed to the mandible over a wide area. The disease appeared to be localized to this area inasmuch as there was no other palpable lymphadenopathy and a roentgenogram of the chest showed no metastases. Biopsy specimen was reported epidermoid carcinoma, grade 1.

On June 6, 1945 a resection of the right mandible and considerable surrounding soft tissue was combined with a right radical neck dissection. It was possible to appose the mucosa but not the skin. The large skin defect was covered with a dermatome graft. The graft took well and the postoperative course was progressing satisfactorily until the 10th postoperative day, when the patient (a known epileptic) became very unco-operative, refused all

Fig. 5. Case 5. Submaxillary mass (derived from a carcinoma of the lower lip) removed with the overlying attached skin. The markers visible on the specimen are placed for the better orientation of the pathologist. Tumor is visible invading along the periosteum though the mandible itself is not yet involved. The ability to spare the anterior portion of the right mandible considerably improves the cosmetic result.

feedings, removed his dressings, and tore loose the mucosal suture line with his fingers. It became necessary to remove him to a hospital for the mentally ill. Microscopic examination of the specimen showed no other node involvement beyond that presented by the conglomerate mass of disease. There was extensive periosteal invasion but no actual invasion of the mandible was seen. An oral fistula persists, but there has been no evidence of recurrent or metastatic disease 16 months later.

Among the 12 patients operated on there were 2 postoperative deaths. One of these occurred from shock in an 83 year old patient in very poor general condition. The other took place from aspiration pneumonia, subsequent to the regurgitation and bronchial aspiration of tube

Fig. 6. Case 2. Extensive carcinoma of the lower lip with submaxillary and submental node involvement bilaterally; *en bloc* removal of the diseased area with most of the horizontal portion of the mandible; entire defect reconstructed with tube graft brought from upper chest wall.

feedings. Autopsy findings in this patient revealed brain changes, which were considered to be of etiologic significance in the patient's inability to handle his feedings. The patient's operative course would relate these to internal jugular vein resection. Apart from the 2 deaths there were no other serious complications.

Postoperative temperatures have usually ranged from 101 degrees F. to 103 degrees F., for the first 3 to 4 days, probably as a result of the natural contamination of so large a wound. No serious infections ensued though occasional collections of seropurulent material, particularly in the pterygoid region, did require drainage. Significance is attached to the fact that most of the patients treated presented lip cancer. It is unlikely that many cases of cancer of the tongue, floor of the mouth, *et cetera* will be found suitable for such an operation as most of these will present other manifestations of more widespread dis-

ease at the stage of fixation of the local nodes to the mandible. Our one case having had a primary cancer of the tonsil was definitely bizarre in its behavior.

There have been three postoperative recurrences. Only one of these occurred among the patients whose disease derived from a carcinoma of the lip (Case 2). In this instance the probability of recurrence was anticipated, for at one point in the procedure, a small but involved lymph node was inadvertently cut across. The recurrence was carefully sought for during subsequent follow-up examinations, and when it appeared was apparently successfully treated by wide excision. The other two recurrences (Cases 1 and 8) took place presumably on the basis of microscopic permeation of lymphatics at some distance from the palpable limits of the disease in patients whose disease it was felt had been widely circumscribed at operation. Both of these represented carcinomas of the buccal mucosa. It is our belief that these recurrences when they take place in an area still amenable to wide surgical removal should be attacked in that manner even though there may be several. Widespread recurrence would rarely lend itself to surgical extirpation.

In 7 patients the disease was apparently confined to the area of obvious clinical involvement as indicated by careful pathologic examination of the specimen and follow-up examination to date. In the remaining 5 however, either examination of the specimen (where total unilateral dissection was permissible) or the subsequent clinical course (where the dissection because of other considerations was subtotal in extent) revealed occult metastatic disease that had been unsuspected at the time of operation. This should certainly justify the accomplishment of complete node dissections whenever feasible on other counts. As might well be anticipated 3 of the 4 patients who presented simultaneously active disease in both the primary tumor and the lymph node sites fell into the group having more widespread node involvement than was clinically apparent. Carcinoma which within a short interval is present in both its primary and secondary sites is silently declaring its aggressiveness.

An apology for removal of the mandible in those cases failing to show roentgenologic evidence of actual bone invasion hardly seems necessary. That bone invasion will occasionally be microscopically demonstrable in spite of roentgen report to the contrary is well exemplified by Case 1.

In the absence of bone invasion, however, wide periosteal involvement has been the rule in our experience when node masses are fixed to the jaw. It is doubtful whether anything less than resection of the mandible is justified under such circumstances.

The duration of follow-up in these patients is still too inadequate to draw any definite conclusions as to actual long term survival. Of the 10 patients surviving operation, 2 have died of intercurrent disease 27 months and 1 month, respectively, from the date last treated and at the time of death were free of any evidence of carcinoma. One died with a recurrence treated by x-ray which developed 7 months following operation. Seven are living and free of any manifestation of recurrent or metastatic cancer by actual examination 43, 30, 25, 19, 18, 16, 16 months, respectively. Certain statements regarding the group surviving free of disease are justified, however, since it will be readily admitted that what life remains for these patients untreated is pitiful in the extreme. Radiation therapy at this stage of the process accomplishes little palliatively, and cures must be very rare; operative treatment can be accomplished with an acceptable mortality. The survival of 7 patients to date has unquestionably justified the effort. Since carcinomas of the type here discussed as a rule give evidence of recurrence or metastasis within 1 year of treatment, there is reason to expect that a fair percentage of those surviving to date free of disease may continue to do so.

SUMMARY

1. Twelve patients are presented in whom a combined jaw resection and neck dissection were carried out for carcinoma metastatic to the upper cervical lymph nodes which secondarily involved the mandible.

2. A natural selection of such cases is indicated by the tendency which some tumors have for prolonged local aggressiveness before

dissemination beyond the limits of surgical removal occurs.

3. Considerations relative to the management of these patients are discussed.

4. The results to date, 2 postoperative deaths, 1 patient died with recurrence, 2 deaths from intercurrent disease without recurrence and 7 patients alive without recurrence from 16 to 45 months after the treatment, suggest an ultimate prognosis far differ-

ent from the relatively hopeless outlook formerly existing for these patients.

THE MANAGEMENT OF PLACENTA PREVIA AT THE CHICAGO LYING-IN HOSPITAL

A Review of 325 Cases during 1931 to 1945

M. EDWARD DAVIS, M.D., F.A.C.S., and ALICE CAMPBELL, M.D., Chicago, Illinois

PLACENTA previa is still one of the major complications of pregnancy and labor but modern management has robbed it of much of the terror of past decades. Early diagnosis, hospitalization, rational obstetrical treatment and the ease of blood and plasma transfusions have decreased the mortality to the vanishing point in our large institutions. However, mortality statistics from the country at large assign 23 per cent of maternal deaths to hemorrhage and at least half of these deaths are due to placenta previa. Many other women who have placenta previa succumb from infection or embolism and find their way into our statistics as puerperal infection deaths. Thus, it is a fair estimate that 15 to 20 per cent of our maternal deaths are the result of placenta previa.

ETIOLOGY

The cause of placenta previa is still unknown. The most plausible theory is that the abnormal implantation probably results from a failure in the mechanism of transportation of the fertilized ovum. Normally, fertilization occurs in the fallopian tube. The fertilized ovum is moved into the uterine cavity at the end of 72 hours but remains free and unat-

tached for the next 4 or 5 days. Normally, the small vesicle remains high in the uterine cavity where it ultimately attaches itself to the endometrium. If environmental forces move the small vesicle downward so that it finally attaches itself in the region of the internal os, placenta previa must result. Many factors may operate to transport the ovum to this abnormal location.

Morton has called attention to the increased decidual response in the region of the internal os in a patient with placenta previa. It is suggested that this marked decidual development in contrast to the meager response high in the corpus may have predisposed to the abnormal placental site.

The fertilized ovum is at no time a free agent but depends on environmental forces to move it down the tube and into the uterus. It cannot select the ideal implantation site but it must attach itself to that location where it finds itself at the time of implantation. This locality may be the abdomen, the fallopian tube, the uppermost portion of the anterior or posterior walls of the uterus or in the region of the internal os. Placentation occurs at the site of attachment. The degree of previa will depend on how close to the internal os the implantation occurs. Abnormal uterine motility, multiparity, decidual development may pre-

dispose to placenta previa only as they may influence the movement of the ovum in the uterine cavity.

The surface area of the placenta may favor a low implantation. In placenta membranacea placental tissue covers most of the chorion as a result of a failure of villi underneath the decidua capsularis to atrophy. Obviously, all or a portion of the internal os will be covered by placenta. Succenturiate lobes may cover a part or all of the os. Lastly, an abnormally large placenta may impinge on the lower uterine segment simply because of its size.

INCIDENCE

The incidence of placenta previa varies in different institutions, from 0.63 to 2 per cent. In a period of over 14 years, May, 1931 to July 1, 1945, 40,961 patients were delivered in the new Chicago Lying-in Hospital and placenta previa was present 325 times, an incidence of 1 in 126 deliveries or 0.79 per cent (Table I). During this period more than 80 per cent of all deliveries in Chicago occurred in hospitals so that the figure represents a fair index of the frequency of this complication. Furthermore, all patients who had bleeding during the last trimester of pregnancy were examined, thereby establishing a diagnosis ac-

The older literature emphasized the fact that placenta previa was a complication of multiparity. The preponderance of large families in these statistics accentuated this idea. The large family is becoming more and more rare and the "grande multipara" is disappearing. However, in Table II, it can be noted that although the deliveries were

almost equally divided between primigravida (45.5%) and multigravida (54.5%) 3 out of 4 patients with placenta previa were multigravida. The distribution of the patients in relation to their parity is indicated in Table II. Childbearing predisposes to the development of placenta previa but the reason for this fact is still obscure.

PATHOLOGY

The abnormal location of the placenta results in a pathologic placental uterine relationship which is responsible for the hemorrhage and the greater vulnerability to trauma and infection. When the placenta is high up in the corpus the placental site develops in the thick myometrium of this region. The vascularization incidental to these changes does not interfere with the integrity of the uterus. A thick decidual buffer zone between the placenta and the uterine wall facilitates the physiologic separation in the third stage of labor. Placental attachment is not disturbed by the uterine motility associated with the development of the lower uterine segment in late pregnancy and dilatation of the cervix in labor.

The lower uterine segment and the cervical region are not adapted to placental attachment. This portion of the uterus is the inactive passage zone between the contractile

TABLE III.—ONSET OF BLEEDING IN PLACENTA PREVIA 1931 TO 1945

corpus above and the vagina below. The walls composed largely of elastic tissue fibers and few muscle cells are designed to withstand considerable distension and stretching. The vascularization of these walls brought about by placental attachment interferes with their normal integrity. Minor manipulations through the cervix may result in extensive lacerations of the pathologic lower uterine segment. The physiologic changes incidental to effacement and dilatation must necessarily interfere with the attachment of the placenta resulting in minute or more extensive separations which are responsible for the painless bleeding characteristic of placenta previa. In that effacement is a process which may extend over a period of days or several months, episodes of bleeding will recur. The initial hemorrhage may occur early in the last trimester or it may be postponed until the onset of labor but bleeding is inevitable in placenta previa.

The proximity of the placental site to the vagina which always harbors organisms and to manipulations necessary for delivery increases the hazard of infection. Trauma, too, invites infection. The loss of blood favors its development. It has been pointed out that fewer women die of blood loss primarily today but the incidence of infection has not been reduced greatly. There is a greater hazard of thrombosis and embolism in placenta previa.

TABLE IV.—AMOUNT OF BLEEDING IN PLACENTA PREVIA 1931 TO 1945

	Complete	Partial	Incomplete		Total
			Marginal	Low lying	
None (elective cesarean section)	11	1	6	4	22

The thrombi in the sinuses of the placental site located in the lower uterine segment are more easily mobilized. The closer association of the placental site and sources of infection favors thrombophlebitis and embolism.

SYMPTOMS

Painless bleeding in the later weeks of pregnancy is pathognomonic of placenta previa. The initial hemorrhage may occur early in the gestation and undoubtedly some abortions are the result of low implantations. These patients never find their way into the statistics on placenta previa. In 39, or 12 per cent, of our patients the initial bleeding occurred prior to 28 weeks, in 53, or 16 per cent, sometime between the twenty-eighth and thirty-second week (Table III). Thus, in 28 per cent of the patients the presence of the placenta in the region of the cervix manifested itself prior to fetal viability. This fact accounts for the high fetal mortality for few babies survive prior to 28 weeks and not many more prior to 32 weeks' gestation. The degree of encroachment of the placenta on the internal os is not the most important factor in determining the time of onset of bleeding. It is apparent from our figures that the bleeding in complete placenta previa began a week or two earlier than in incomplete placenta previa. Marginal or low insertion of the placenta may not result in any bleeding prior to the onset of labor. The onset of efface-

ment of the cervix as well as the uterine motility which is responsible for it rather than the degree of placental coverage of the internal os determines the onset of bleeding.

The severity of the hemorrhage will be determined by the extent of the previa and whether or not the patient is in labor. The initial bleeding is rarely alarming and may subside quickly. It may consist of a few drops or the blood may gush out for a moment. In that the bleeding is dependent on a tear through maternal sinuses by minute separations, the size of the vessel will determine the blood loss. The initial bleeding usually subsides quickly in the patient not in labor, but bleeding will recur in days or weeks. A small amount of bleeding may persist for days to give way to a dark serosanguineous discharge. The onset of labor brings on rapid cervical effacement and dilatation and the hemorrhage becomes more profuse or if it has subsided it will recur. Again, the hemorrhage may be moderate or profuse depending on the rapidity and the extent of placental separation.

In Table IV, it will be noted that 35 patients had a profuse hemorrhage prior to their examination and treatment. Eight more patients were in shock when they entered the hospital. Thus, in 13 per cent or in 1 out of 8 patients the blood loss was serious prior to the institution of treatment. In 22 elective cesarean sections that were performed for indications other than placenta previa, the placenta was encountered in the lower uterine segment covering part or all of the os. In these patients the abnormal location of the placenta incited no bleeding. It is probable that had labor intervened prior to the operation, bleeding would have occurred incidental to effacement and dilatation.

DIAGNOSIS

The diagnosis of placenta previa must rest to a large extent on its pathognomic symptom—painless bleeding in the last trimester of pregnancy. This warning hemorrhage, small or considerable in amount, must invariably call attention to the likely presence of the placenta in an abnormal location. Every patient who complains of bleeding is referred to the hospital for a diagnosis as to the cause. After it has been made certain that blood is available read-

ily in the event transfusion should be indicated, the patient is examined vaginally.

If the cervix is partially effaced and the os admits the finger there is no difficulty in palpating the placenta when it covers part or all of the os. In the low lying placenta the edge can be palpated easily if it reaches within several centimeters of the internal os. In the absence of the placenta the thin membranes are the only barrier between the palpating finger and the presenting part. No anesthesia is necessary for this simple examination. An antiseptic lubricant, such as merthiolate in glycerin, may add to the ease with which the examination is carried out and to its safety.

Abdominal examination may reveal a transverse presentation or the presenting part above the inlet of the pelvis. The presence of the placenta in the lower uterine segment may interfere with the normal accommodation of the head in the pelvis, particularly if the latter is small or abnormal. The abnormal presentation and the failure of engagement of the presenting part is additional evidence of placenta previa in the patient with painless bleeding.

Direct or indirect visualization of the placenta has been used in the diagnosis of placenta previa. Snow and Rosensohn, Brown and Dippel have described a method of filming the uterus to emphasize the variable densities of the soft tissues. If the placenta is ideally located its shadow can be visualized clearly on the x-ray plate in 3 out of 4 patients. The absence of a placental shadow does not rule out placenta previa. Ude, Weum, and Urner have injected radiopaque substances into the bladder and Prentiss and Tucker have used air to provide greater contrasts and the placenta has been visualized as an intervening shadow between the bladder and the presenting part. Both of these methods have been used experimentally at the Chicago Lying-in Hospital, but they have not become a part of our routine because they do not add appreciably to the management of this complication. Pelvic examination affords the opportunity to determine the degree of placenta previa, the state of the cervix, the adequacy of the pelvis and the fetal position. These findings are necessary in a decision as to the appropriate treatment.

In the differential diagnosis of placenta previa all causes of bleeding in the last trimester of pregnancy must be ruled out. We have kept a record for a 5 year period of all vaginal examinations for bleeding during the last 3 months of pregnancy and found placenta previa in 32 per cent of the cases. Many causes, most of them trivial, were responsible for the bleeding in the other patients. The bleeding in abruptio placentae is most often associated with pain but mild degrees of placental separation can occur in the absence of pain and marked uterine tenderness. Painless bleeding can occur from an abnormal cervix, the site of an erosion, a polyp, or, rarely, a malignant lesion. Vaginal varices may rupture and bleed. Trauma of the vaginal walls physiologically altered or inflamed as a result of a lower genital tract infection may result in bleeding. At times the painless bleeding may have its origin in the urethra and bladder or even the rectum. A careful vaginal examination combined with the visualization of the vagina and cervix by means of a speculum will identify the origin of the bleeding most often. Rarely, no cause for the bleeding can be found or the examination is inadequate to rule out placenta previa. In 33 patients no placental tissue could be palpated at the initial examination. However, when they returned to the hospital because of a recurrence of painless bleeding, sufficient changes had taken place in the cervix so that placenta could be palpated.

There are various degrees of previa depending on the extent that the os is covered by placenta at the time of the examination. Complete placenta previa is used to designate complete coverage of the os and incomplete placenta previa partial coverage. At times no placenta is palpable directly over the internal os but it extends into the zone of effacement and dilatation. As the lower uterine segment develops during the latter part of pregnancy and in labor, the dependent portion of the placenta may become separated and cause bleeding. These low insertions of the placenta must be considered as borderline placenta previas. Obviously, the relationship of the placenta and the internal os may vary as effacement and dilatation progress but clinically this classification will suffice. The term,

central placenta previa, which denotes that the os is covered by the central portion of the placenta, is no longer applicable for this diagnosis can be made only at cesarean section. Total coverage of the os by placenta at or near complete dilatation is encountered rarely on the large maternity services.

TREATMENT

The treatment of placenta previa has become standardized in the large institutions in recent years. Advances in medicine and in obstetrics have contributed to the present management. No one questions the fact that all patients who bleed in the last trimester of pregnancy should be sent to a hospital for diagnosis and treatment. There is no home treatment for this serious complication.

The treatment of an obstetrical complication identified with blood loss begins in the prenatal period. Each patient should have a careful blood study which should include the determination of the hemoglobin content, the cell volume, Rh reaction, and the Wassermann or Kahn. The patient in whom the hemoglobin remains under 10 grams in spite of iron therapy should be transfused before she goes into labor or suitable blood should be available readily. One cannot always guard against an excessive blood loss but facilities should be at hand for the restoration of blood with a minimum of time loss. Plasma should be available at all times but the armed services have emphasized recently what we have known for a long time that plasma does not replace whole blood in serious hemorrhage.

When blood has been made available and preparations for delivery are complete the patient should be examined vaginally. The state of the cervix should be determined, the presence of placenta over the os and the extent of coverage noted. If the os is free of placenta the adjacent walls of the lower uterine segment should be carefully explored for a low lying placenta. Position can now be determined. Lastly, one should evaluate the state of the soft parts and the size of the pelvis.

If no placenta is palpable, a speculum examination of the cervix may help to rule out the cause of the bleeding. In the absence of

placenta previa the patient may be sent home for the examination is unlikely to start labor prematurely.

The initial management of placenta previa is directed toward the control of further bleeding and the delivery of the patient by the most conservative procedure consistent with her safety. When a diagnosis of placenta previa has been established the termination of the pregnancy is indicated. It is recognized that in many patients the baby has not reached a period of development when it can survive out of the uterus. However, the continuation of the pregnancy is fraught with danger and has resulted in an increased hazard for the mother. The primary risk of hemorrhage can be combatted these days by keeping the patient in a hospital where blood is available readily. However, the increased hazard of infection in the presence of vaginal bleeding is still difficult to overcome. It is possible that the use of the new antibiotics prophylactically may some day alter our present routine that once placenta previa is diagnosed the patient should be delivered but that day has not arrived.

The initial management of our patients is summarized in Table V. In a very small number, 22 patients, or 7 per cent of the total,

TABLE VI.—TERMINATION OF LABOR IN PLACENTA PREVIA 1931 TO 1945

labor was in progress when they were admitted to the hospital. Almost 93 per cent were not in labor but entered the hospital because of bleeding. All of our patients are cautioned about the importance of bleeding in pregnancy so that they are seen at the first warning bleeding. Rupture of the membranes sufficed to control bleeding in 98 instances although all but 8 of these patients had incomplete placenta previa. In 99 other cases some additional procedure had to be instituted. Again, in only 14 of these patients complete placenta previa was diagnosed. Thus, rupture of the membranes alone or combined with some other procedure was the initial treatment for the control of bleeding and the institution of labor in 197 patients or 60.6 per cent of this entire series. Cesarean section was the initial treatment in the remainder.

Complete placenta previa is treated by cesarean section. This method offers the best prognosis for the baby as well as for the mother. Abdominal delivery is indicated in incomplete placenta previa when there has been a serious blood loss; when the cervix is long and uneffaced, unripe so to speak; in the elderly primipara in whom the fetus is of great importance because the mother is near the end of her reproductive period; in the patient with a borderline or grossly inadequate pelvis.

At the Chicago Lying-in hospital the low or cervical cesarean section, laparotrachelotomy, is the operation of choice. It has been suggested that the classic operation would miss

the placenta in the lower uterine segment. There is an increased loss of blood if one encounters the placenta on the anterior wall in the lower uterine segment operation but average care, speed and dexterity will keep the blood loss at a minimum. Furthermore, bleeding from placental sinuses can be readily controlled by direct suture, thereby minimizing the possibility of continued bleeding. The entire placental site on the posterior as well as the anterior wall can be inspected easily and bleeding controlled by pack or suture if necessary.

Incomplete placenta previa can be managed in such a way that delivery can be completed through the birth passages in most instances. If the cervix is partially effaced and the os patulous the membranes are ruptured. This simple device will control bleeding in the majority of the patients by allowing the placenta to remain attached to the lower segment as retraction progresses. The presenting part may descend with the escape of the liquor amnii so that it more closely approximates the placenta exerting pressure upon it and helping to check bleeding. Lastly, the rupture of the membranes in a patient with a ripe cervix is the most effective method of inducing labor.

If simple rupture of the membranes does not suffice to control bleeding in incomplete placenta previa, the use of Willett's method can be considered. Scalp traction is effective for the control of bleeding. Willett's forceps or two tenaculae properly applied to the scalp will not result in serious trauma. The viable fetus will usually survive and the scalp damage can be treated. Traction should be applied to the forceps by some contrivance and the least amount of pull necessary to control the bleeding should be exerted. Usually $\frac{1}{2}$ to 1 pound weight over a pulley will suffice.

Cesarean-hysterectomy has been reserved for patients admitted to the hospital potentially or obviously infected, in whom the termination of reproduction is no great loss. The removal of the uterus decreases the hazard of serious infection, for this organ can serve as the focus of a puerperal infection. Extraperitoneal operations, such as the Water's procedure, are of questionable value in these

patients because the abnormal location of the placenta leads to increased vascularity of the lower uterine segment and bladder. This would increase the difficulty for the approach to the baby is through this vascularized zone. There may be some other indication for hysterectomy such as neoplasms of the uterus. The operation is not difficult and with care the blood loss can be controlled. Recovery is usually uneventful.

Table VI presents a summary of the modes of delivery in our group of patients. Abdominal delivery was carried out in 143 or 44 per cent of the patients. Ninety-three patients delivered naturally and in 89 some operative procedure was necessary to terminate the delivery through the natural passages. Thus, more than half of the patients were delivered from below without mortality. This fact emphasizes the importance of individualizing the treatment of this complication.

Some of the accepted methods of treatment in placenta previa made honorable by tradition have no place in the modern hospital. They represented the best that were available in their day but progress has made them obsolete. They still appear in the standard textbooks of our time to confuse the student and practitioner.

Tamponade has no place in the treatment of placenta previa. Even as a temporary expedient to check hemorrhage it is ineffective and dangerous. Patients with placenta previa who are not examined are not likely to bleed to death. Thus, the patient who has bleeding in the later weeks of pregnancy should be referred to a hospital promptly. All examinations should be postponed until everything is in readiness to cope with any emergency.

The bag or colpeurynter can be discarded in the management of placenta previa. It provided a means of controlling hemorrhage but the manipulation incidental to the introduction of the bag and the subsequent delivery often resulted in trauma, infection, thrombosis and embolism.

The introduction of a foreign body in close proximity to the placental site increases the hazard of serious infection. Properly placed, bleeding will be controlled but labor must be initiated and hours may lapse before there is

TABLE VII.—THIRD STAGE OF LABOR IN
PLACENTA PREVIA 1931 TO 1945

sufficient dilatation for the bag to pass through the cervix. The mechanism of labor may be abnormal because the period of the gestation is not favorable to the artificial termination of the pregnancy through the natural passages. Once the bag is in the vagina it must be removed promptly for it no longer acts as a tampon against the placenta. It actually plugs the vagina and much blood can accumulate behind it without the attendant being aware of the continued hemorrhage. When the bag has been removed spontaneous delivery of the child rarely follows. The accoucheur must deliver the baby by version and extraction or forceps. All of these manipulations carried out through a pathologic lower uterine segment, highly vascularized and easily traumatized must result necessarily in serious damage and infection. These factors contribute to increased morbidity and mortality in use of the bag for placenta previa.

Braxton Hick's version was a means of controlling hemorrhage at a sacrifice of the fetus. It was an expedient that had to be resorted to when other methods were less safe. There are several reasons why this method of controlling hemorrhage is hazardous. Braxton Hicks' version was the method of choice in the patient prior to or at the borderline of viability. Under such circumstances the cervix was usually long and at best partially effaced, dilated sufficiently to admit two fingers. The version is difficult under these circumstances even though the accoucheur has had considerable experience. Manipulations result in trauma to the placental area and increased likelihood of infection. Blood loss may be considerable during the process.

TABLE VIII.—SUPPORTIVE TREATMENT IN
PLACENTA PREVIA 1931 TO 1945

Intravenous fluids	17	7	15	0	49
1 transfusion	31	17	21	13	82
2 or more transfusions	4	6	4	1	15

The version completed and bleeding brought under control heralds the onset of an indefinite period during which labor must be initiated and complete dilatation secured. In this period of pregnancy the uterus may be unresponsive and uterine contractions desultory. Hours may elapse before the patient can be delivered during which time trauma and infection are real dangers. The delivery of the fetus may be followed by an abnormal placental stage.

It is apparent that the period of pregnancy best suited for delivery by Braxton Hicks' version is the least favorable for a delivery from below. The unripe cervix, the pathologic lower uterine segment, and the uncoordinated uterine motility may all combine to make the delivery of even a small fetus a virtual nightmare. The highly vascularized cervix may tear like wet blotting paper. Infection may be difficult or impossible to control. Many obstetricians have hesitated to do a cesarean section in the patient with placenta previa in whom the fetus is of questionable viability. The decision concerning the mode of delivery should rest on the degree of placenta previa, the state of the cervix, the parity of the patient and the adequacy of the pelvis. If the baby is sufficiently mature to survive so much the better but its fate is of secondary importance. However, the number of premature babies who will survive delivery will be greater by cesarean section than by other methods.

THE PLACENTAL STAGE

The third stage of labor following delivery through the birth canal deserves special consideration. The abnormal location of the placenta may lead to incomplete separation and to continued bleeding from sinuses in the lower uterine segment or from trauma. There are too few muscle cells in the lower segment to produce normal contraction and retraction of the placental site, thereby interfering with placental separation. The same lack of musculature may prevent the normal closure of uterine sinuses. The proximity of the placental site to the vagina and sources of infection increases the hazard from this source.

The phase of placental separation can be expedited by the administration of ergonovine intravenously as the baby is being delivered. At least thirty seconds should elapse from the time the drug is injected until the baby is delivered in order that the ergonovine can exhibit its action. Usually the placenta separates promptly with the passage of the infant out of the uterus and it should be expressed. If separation is delayed in the presence of bleeding the placenta should be removed manually. Invasion of the uterus is not without risk but if carried out with proper regard to asepsis it is far less dangerous than continued blood loss. Continued bleeding after the placenta is out of the uterus calls for a careful exploration of the uterine cavity for a retained fragment of placenta as well as an examination of the lower uterine segment and vagina for trauma. Lacerations which bleed should be sutured. Bleeding from the placental site may have to be controlled by a uterine pack. Tamponade should begin in the corporeal cavity, extending into the lower uterine segment and include the vagina.

It will be noted in Table VII that manual removal of the placenta was indicated in 36 instances. Uterine tamponade to control continued bleeding was necessary in 15 patients. Neither method sufficed in 5 patients for they continued to bleed and hysterectomy had to be performed. This major procedure can be life-saving if the delay is not too great. The patient who continues to bleed in spite of a well placed uterine and vaginal pack and the patient in whom bleeding from trauma cannot

TABLE IX.—MORBIDITY IN PLACENTA PREVIA

be controlled by suture should have adequate replacement of blood and an immediate hysterectomy.

SUPPORTIVE TREATMENT

The ready availability of blood and plasma has been the most important contributory factor in the great improvement in the prognosis of placenta previa. The ability to replace blood loss promptly has influenced our therapy of all obstetrical complications associated with hemorrhage. Every maternity must have available a source of blood for the time factor in the replacement of blood is of the utmost importance. Plasma will maintain the circulation for a short period but blood or red cells are necessary for the patient who has had an exsanguinating hemorrhage. In Table VIII it will be noted that 139 patients or 49.3 per cent of all patients with placenta previa received at least one transfusion and that 21 patients had two or more transfusions.

The hospital that has a blood bank is in an ideal position to provide ample amounts of blood readily. The smaller maternity should have facilities for the typing and matching of patients and donors at all times. A list of donors among the personnel, particularly those in blood group O should be posted in the

PROGNOSIS

delivery room. Rh negative blood or donors should be available for the Rh negative patient. Blood loss in placenta previa may necessitate more than one transfusion and it is more than possible that a patient may be sensitized by the transfusion of Rh positive blood. These smaller institutions should stock plasma which can be administered while blood is secured. The State Health Departments are making plans to supply blood and plasma to hospitals so that this need may be met. It was possible to build up a world wide organization to supply blood to our troops in time of war and it should be possible to use our experiences to extend this boon to our civilian population in times of peace.

Parenteral fluids are valuable in the treatment of hemorrhage but they should be administered in conjunction with blood and not in place of it. Ringer's or saline solution can be given subcutaneously in liberal amounts. The intravenous use of hypertonic glucose solutions should be restricted until blood is available. In an emergency 500 cubic centimeters of a 20 per cent glucose solution will raise the blood pressure and help to maintain the circulation temporarily but a secondary and a more serious drop in blood pressure may ensue unless blood is administered.

The prognosis for the mother in placenta previa has improved to such an extent that deaths from placenta previa should be almost preventable in an urban community. The mortality from this complication can be kept below 1 or 2 per cent by making use of all the knowledge that is available today and the facilities of the large maternities. The morbidity and mortality in this group of patients are listed in Table IX. The overall morbidity of 22 per cent can be improved by greater care in the management of this complication. These patients were treated over a period of more than 14 years and many changes have occurred in the therapy of some of the complications listed under morbidity.

The danger of infection and thrombophlebitis is emphasized in our statistics. Together they accounted for the morbidity in 57 of the 72 patients. Sulfa drugs and antibiotics have decreased the hazard of infection to some extent in the last few years but much remains to be accomplished along these lines. Twenty of our patients, including the fatal case, developed thrombophlebitis. Infection predisposes to thrombosis but the location of the placental site is the most important contributory factor. Measures to combat thrombosis have not been used extensively and are still on trial. Much more investigative and clinical observations are necessary to extend the use of the several anticoagulants to obstetrics.

The maternal mortality in this group of patients was 0.6 per cent. Résumés of the histories of the 2 patients who died follow:

M. H., No. r60045, aged 33 years, tripara, quintigravida, r abortion, was first examined when 20 weeks pregnant. History and physical findings were essentially normal. At 37 weeks there was painless bleeding and vaginal examination revealed marginal placenta previa. At 37½ weeks sudden profuse hemorrhage of 600 cubic centimeters occurred. Laparotrachelotomy with tubal ligation was carried out under local anesthesia. On the 3rd postoperative day her temperature was 38.8 degrees, and cough and râles in the left lower lobe were present. On the 9th postoperative day she had continued fever, pain and swelling in the left leg. On the 10th postoperative day there was present moderate purulent discharge from the wound. On the 14th day she had pain in the left chest and râles, temperature was 38.5 degrees and pulse 100. On the 16th day her condition was unchanged; however, at noon she developed sudden dyspnea, cyanosis, weak rapid pulse, cold clammy skin, but no evidence of acute pulmonary edema, and expired. Autopsy revealed bilateral massive acute pulmonary embolism and old infected pulmonary infarcts.

M. D., No. 65906, aged 37 years, tripara, quadrigravida, 1 stillbirth, anemia in 1937, was first examined when 18 weeks pregnant, at which time she had varices and monilia vaginitis. When 40 weeks pregnant she was admitted for study; hypertension: 170/120. At 41 weeks medical induction failed; bleeding was 75 cubic centimeters. Vaginal examination revealed total placenta previa. Laparotrachelotomy was carried out under local anesthesia; incision through placenta with marked bleeding, 600 cubic centimeters. Manual removal of placenta, tight packing. At time of skin closure, the blood pressure could not be obtained. Patient given caffeine, ephedrine, fluids, transfusion; 2000 cubic centimeters of blood expressed from uterus; second transfusion given. Respirations shallow, pulse weak, blood pressure 0. She expired 2 hours after operation. Autopsy showed exsanguination, atelectasis of both lower lobes, meconium in pulmonary vessels, fatty changes to liver.

Both of these deaths have been classified as preventable by our staff. The patient who died of hemorrhage bled profusely throughout the operation without anyone in attendance being aware of the gravity of her condition. More clinical experience on the part of the obstetrician would have prevented this fatality. The second patient was admitted to the hospital because of painless bleeding and a diagnosis of placenta previa was made on vaginal examination. The termination of the pregnancy was delayed 4 days when a sudden pro-

fuse hemorrhage of 600 cubic centimeters necessitated abdominal delivery. She developed a puerperal infection, pelvic thrombophlebitis and succumbed from a pulmonary infarct on the sixteenth day. It is possible that the termination of the pregnancy at the time the diagnosis of placenta previa was established would have decreased the hazard of infection and the subsequent thrombophlebitis. Delivery 3 or 4 days after a vaginal examination in a patient with placenta previa is a most inopportune time in regard to the hazard of infection.

The prognosis for the baby in placenta previa is serious as the statistics in Tables X and XI indicate. Of 329 babies who were born to the 325 mothers, 225 or 68.4 per cent were discharged from the hospital alive. The 104 babies who did not survive were equally divided between stillbirths and neonatal deaths.

The most important cause for the failure of the baby to survive was prematurity. Our policy of terminating the gestation promptly when the diagnosis of placenta previa is established must necessarily result in the sacrifice of many babies too young to survive an extrauterine existence. Only 1 baby of 29 weighing less than 1000 grams survived although 10 were delivered alive. In the group weighing 1000 to 2500 grams there were 179 babies of whom 95 were born alive but only 62 or 65.3 per cent of these survived. However, babies weighing more than 2500 grams fared much better for 172 of 181 were born alive and 162 or 94.2 per cent of these survived and were discharged from the hospital.

Up to the present time the previable and the premature baby have been considered expendable in order to insure the greatest possible safety for the mother. The dangers of hemorrhage, infection, and thrombophlebitis preclude the continuation of the pregnancy in the patient in whom placenta previa is diagnosed. It is possible that this viewpoint may change. The patient who remains in a hospital where blood can be administered readily may run little risk from serious blood loss. The prophylactic use of the newer antibiotics may decrease the hazard of infection. Cesarean section provides a safer method of delivery for the premature fetus than delivery through

the pelvis. However, we must never lose sight of the fact that once a cesarean is performed future deliveries must be by the abdominal route. All of these factors will have to receive their proper weight in any future decision to change our present management which has yielded such excellent results for our mothers.

CONCLUSIONS

Placenta previa is still a major cause of morbidity and mortality but modern management has robbed this condition of much of its terror. It has been possible to deliver 325 consecutive patients with placenta previa during the years 1931 to 1945 with a maternal mortality of 0.6 per cent.

The following procedure is followed at the Chicago Lying-in Hospital. All patients who have vaginal bleeding late in pregnancy are referred to the hospital for examination, diagnosis, and treatment. When suitable blood is available, a vaginal examination is carried out to determine the presence of placenta previa, its extent, the condition of the cervix, fetal position, the adequacy of the pelvis and the state of the soft parts. These factors plus the age, parity, and the physical condition of the patient will determine the choice of treatment for the control of bleeding and delivery. Some of the accepted methods of treatment made honorable by tradition have no place in the modern hospital.

CAUSALGIA

A Study of 75 Cases

JACK L. ULMER, M.D., F.A.C.S., Major, M.C., A.U.S., Richmond, Virginia, and

FRANK H. MAYFIELD, M.D., F.A.C.S., Lieutenant Colonel, M.C., A.U.S., Cincinnati, Ohio

THE term "causalgia" was first used by Mitchell, Morehouse, and Keen in 1864 to designate a bizarre symptom complex occurring after injury to peripheral nerves. The main features of this symptom complex are severe burning pain and hyperesthesia, in association with trophic and vasomotor changes in the injured extremity. Little is known about the fundamental cause of this condition, and the theories advanced to explain it are so numerous that no attempt shall be made to develop them. Suffice it to say that in certain individuals following injury to one or more peripheral nerves a painful reflex mechanism is set in motion which is accompanied by abnormal vasomotor activity, manifested by varying degrees of vasodilatation or vasoconstriction. Relief can be obtained in most instances by surgical interruption of the appropriate sympathetic pathways.

In this paper we present the data from 75 patients who showed this symptom complex. Fifteen of these cases have previously been reported by one of us, with Captain Devine (3). These 75 cases were encountered in a series of 1,477 peripheral nerve injury cases admitted to the neurosurgical service of Percy Jones General Hospital from January 15, 1943, to May 31, 1945, an incidence of approximately 5 per cent. Three patients were officers and 72 enlisted men. The ages ranged from 19 to 39 years.

The peripheral nerve injury was incomplete in every instance and resulted from penetrating shell fragment or bullet wounds. The sciatic nerve was involved in 29 cases; the median in 16 cases; the brachial plexus (pre-

dominantly the lateral and medial cords) in 13 cases; the median and ulnar in 8 cases; the median, ulnar, and radial in 3 cases; the tibial and peroneal (below the knee) in 2 cases; the tibial in 2 cases; the median and radial in 1 case; and the femoral nerve in 1 case. The nerve injury was proximal to the elbow or knee in 66 cases (88 per cent) and distal in 9 cases (12 per cent). No patient had accompanying major vascular injuries.

In 44 of the 75 cases the burning pain developed immediately after the injury, in 14 within the first 48 hours, and in the rest (17) in from 72 hours to 2 months. The symptoms had been present for periods of time ranging from 3½ weeks to 15 months. The majority of patients were treated within 4 months from the time of injury.

SYMPTOMS AND SIGNS

The cardinal symptom in each case was burning pain of a throbbing or aching character. The pain was always referred to the distal part of the involved extremity and was not confined to the autonomous zone of the injured nerve though it was usually more intense in that zone. In the hand it was referred chiefly to the palm and fingers; in the foot, to the instep, sole, and toes. The intensity varied from less severe states to the unbearable. The pain was continuous but subject to exacerbation by the slightest emotional or physical stimulus, and most of these patients appeared in a perpetual state of defense and went to absurd extremes to protect the painful limb. The severity of the pain rendered an accurate assessment of the nerve injury impossible in many cases.

The vasomotor manifestations were of two types, vasodilatation and vasoconstriction, and in no case was there noticeable alteration

*The first 25 of the 75 cases were summarized in a previous publication (3).

in the type while the patient was under our observation. The skin of those in vasodilatation was usually reddish, dry, scaly, and warmer than that of the normal extremity and the hair long and coarse. The skin of those in vasoconstriction was usually cold,

thin, and glistening, and sweated profusely. In this group there was usually loss of hair, tapering of the digits, and trophic changes in the nails.

Sixty-eight of the 75 patients obtained some relief from the application of moisture. Thir-

ty-eight preferred cold water; 30, warm water; and 7 noted no significant effect of moisture. It seemed that warm water gave relief where there was vasoconstriction and cold where there was vasodilatation.

Most of these extremities showed gradations of joint stiffness brought on by painful splinting and disuse. This was one of the greatest residuals after the relief of pain but proved amenable to physical therapy if treated early.

In the more severe cases, the patients were usually malnourished because of low food-intake.

Most of these patients were irritable, shut-in, critical of attendants, and showed no interest in family or friends even though they had been overseas for many months. Their facial expression manifested evidence of anxiety, weariness, and distress. These findings suggested that the disorder might be functional, so psychiatric examinations were carried out in some of our patients before and after operation. After relief of the pain, all appeared essentially stable and normal, and without exception they became pleasant, co-operative, and happy. In our patients there was no evidence of any definite predisposing constitutional factor responsible for the development of this syndrome.

There appeared to be no correlation between the severity of the nerve injury and the intensity of symptoms. The nerve lesion was incomplete in each case.

METHODS OF STUDY

These patients were studied to correlate subjective symptoms and trophic disturbances with blood flow in the injured part. Blood flow was determined by means of oscillometric and skin temperature readings in the first 15 cases and by skin temperature readings alone in the rest. Those in vasodilatation usually showed skin temperature readings from 1 to 4 degrees higher than readings of corresponding areas of the normal extremity; those in vasoconstriction showed readings from 2 to 6 degrees lower.

One patient in vasoconstriction developed malaria (*Plasmodium vivax*) and during the periods of elevation of temperature was com-

pletely free of pain. The pain returned, however, when the malaria was controlled. Because of this observation, artificial fever therapy was tried in 5 patients, 1 of whom remained well after 3 treatments. The others received as many as 5 treatments, with relief for the period of elevated temperature only. Subsequent sympathectomy was followed by relief in these 4 patients.

X-ray film of the painful part was made in 20 cases. Each showed some degree of demineralization of the small bones of the hand or foot as contrasted to the normal. The changes were most marked in those in vasodilatation. However, the demineralization appeared no more pronounced than in some cases of comparable nerve injuries without causalgia.

TREATMENT

Seventy-two of our patients were treated by surgical procedures, 70 by surgical interruption of the sympathetic chain, which included preganglionic ramisectomy of the second and third dorsal ganglia for the upper extremity and removal of the second and third lumbar ganglia for the lower extremity. Sixty-three of the 70 were cured by the initial operation.

Two patients with severe but incomplete lesions of the sciatic nerve were treated by resection of the injured segment and neurorrhaphy. This procedure relieved the pain in both instances.

In every case, procaine block of the appropriate sympathetic ganglia was done before definitive treatment was carried out. This procedure invariably gave immediate and dramatic relief of the pain for periods ranging from 1 to 3 hours, but in most patients it reached its previous intensity in a very short time. In a few, partial relief persisted for several days. During the period of remission, the patient became co-operative and permitted a more thorough sensory and motor evaluation of the involved extremity, whereas examination was unreliable before the pain was relieved. Frequently, where no motor function had been observed previously, the patient began to move the extremity immediately. This suggested that in some of the

cases the pain had initiated a reflex paralysis (Livingston).

Since numerous reports have been made of permanent cures from one or more sympathetic blocks, some patients were injected 4 to 8 times. There was always immediate relief of the pain, but no patient obtained complete and permanent relief from this procedure. However, the sympathetic block served two useful purposes: First, by relieving the pain temporarily it permitted a more accurate evaluation of the nerve injury; and second, it established the indication for sympathectomy. In the last 55 cases, this procedure was used for diagnosis only.

Neurolysis was done in 5 cases and periarterial sympathectomy at the level of the injury in 3 cases, but the pain was not influenced by these procedures. Later these patients were sympathectomized with relief.

SPECIAL CASES

Seven patients were not completely cured by the initial operation on the sympathetic chain but 4 were cured by subsequent operations. These deserve special comment.

Three patients with high sciatic injuries (buttock or above) obtained partial relief after removal of the second, third, and fourth lumbar ganglia. Later removal of the first lumbar ganglion resulted in complete relief.

Another patient with a similar lesion had the first, second, third, and fourth lumbar ganglia removed initially. Following this he was completely relieved of pain for 72 hours, when moderate pain recurred. Paravertebral procaine blocks at the level of the eleventh and twelfth dorsal vertebrae gave immediate and complete though temporary relief on two occasions. A starch-iodine test demonstrated sweating over the buttock, leg, and dorsum of the foot. It was concluded that some sympathetic fibers to the injured segment of nerve remained. The eleventh and twelfth dorsal ganglia were removed by resecting the twelfth rib. At this operation the diaphragm was sectioned to verify that the upper lumbar chain had been removed. Complete relief followed.

A similar patient with a sciatic lesion at the buttock had the second, third, and fourth

lumbar ganglia removed, followed by incomplete relief. Procaine block at the level of the first lumbar vertebra gave temporary relief. The first lumbar ganglion was then removed without benefit. Procaine injection at the eleventh and twelfth dorsal vertebrae gave complete relief on two occasions. With this evidence plus the fact that sweating persisted in the location of the pain and also at the level of the injury, the eleventh and twelfth dorsal ganglia were removed and complete relief followed.

Two patients with lesions of the upper extremity had the third and fourth dorsal ganglia interrupted instead of the second and third because of mistaking the fourth rib for the third in the exposure. This produced only partial interruption of the sympathetic supply to the involved limb and these patients were only partially relieved. The first patient was then relieved by a neurorrhaphy of the median nerve. In the second case neurolysis of the eighth cervical and first dorsal roots did not affect his symptoms. However, he has since improved to the point where no further surgical interference seems indicated.

DISCUSSION

In each case of this series, symptoms resulted from high velocity missile wounds of large mixed peripheral nerves and we feel that they represent true causalgia. For a time it was felt that causalgia was a distinct entity, but the underlying disorder is no doubt related to that of a heterogeneous group of painful posttraumatic dystrophies, including Sudeck's atrophy, posttraumatic painful osteoporosis, and other so-called minor causalgias (Homans). The chief difference is one of degree, perhaps, varying with the size of the nerve involved.

The vasomotor disturbance was of two types, vasodilatation and vasoconstriction. Forty patients of this group were in vasodilatation and 35 in vasoconstriction. The subjective symptoms were identical but the objective signs varied, yet interruption of the sympathetic chain relieved the pain in both groups. Therefore, it would appear that alteration of blood flow was not responsible for the pain.

In the majority of our cases the intense burning pain occurred immediately after the injury, which rules out infection and irritative scar formation as significant etiologic factors. In fact, with rare exception the traumatic wounds healed without gross infection.

The trophic manifestations in some cases were essentially the same as those seen in comparable nerve injuries without causalgia, but the secondary joint changes with resulting fibrous ankylosis were more severe because of voluntary immobilization of the painful extremity.

Seven patients of this group failed to obtain complete relief from the initial operation upon the sympathetic chain. Five were patients with wounds involving the sciatic nerve at the buttock or above. Removal of the second and third lumbar ganglia had been effected in each case. Subsequent removal of the first lumbar ganglion in 3 of these resulted in complete cure. In 2, removal of the eleventh and twelfth dorsal and first lumbar ganglia were required. In the other 2 cases which involved the upper extremity, incomplete sympathectomy was done at the initial procedure when the fourth rib was removed instead of the third. One patient was then relieved by neurorrhaphy of the median nerve. In the other case, neurolysis of the eighth cervical and first dorsal roots did not affect his symptoms. However, he has since improved to the point where no further surgical interference seems indicated.

Those patients not relieved by the initial sympathectomy showed evidence of incomplete sympathetic denervation, not only to the area of referred pain, but to the area of injury. This was verified by sweating in these areas as shown by starch-iodine tests and evidence of lowered skin resistance to electrical conduction. This has been more noticeable in the cases involving the lower extremity where the injury was high in the thigh.

From these observations, it would appear that the sympathectomy must include the injured segment of nerve. However, the possibility of anomalies of the sympathetic chain must be considered. It can be stated that removal of the second, third, and fourth lumbar ganglia may be inadequate for lesions high in

the thigh. In these cases it may be necessary to remove the first lumbar as well as the eleventh and twelfth dorsal ganglia. For lesions of the upper extremity preganglionic sympathectomy of the second and third dorsal ganglia is necessary. The segment of the sympathetic chain removed has been identified postoperatively by x-ray examination through the use of a metallic clip on the proximal end of the chain when the lumbar operation was done and identity of the rib removed when the dorsal operation was done.

Various medical and surgical treatments have been advocated for the cure of causalgia but in our experience surgical interruption of the appropriate sympathetic ganglia has been the most effective procedure. It has provided relief in each case and has the advantage of carrying a minimal penalty, in contrast to more radical surgical procedures such as regional injection of alcohol, rhizotomy, and chordotomy.

SUMMARY AND CONCLUSIONS

The data from 75 cases of causalgia due to war wounds of large mixed peripheral nerves have been presented and the following conclusions are drawn.

1. The pathologic mechanism is obscure.
2. The disorder is characterized by burning pain in association with vasomotor disturbances in the distal part of the extremity.
3. The vasomotor disturbances are of two types, vasoconstriction or vasodilatation. The possibility that the vasomotor state may vary in any case is recognized but has not been observed.
4. The pain can be relieved by appropriate sympathectomy. The sympathectomy must be complete, however, and with lesions involving the upper portion of the sciatic nerve removal of the sympathetic chain as high as the eleventh dorsal ganglion may be required. For lesions of the upper extremity preganglionic operation is adequate.
5. Procaine block of the appropriate chain is a necessary diagnostic procedure.
6. Repeated procaine block as a therapeutic agent has not been effective in our hands. Certain patients have improved with this procedure, but none has been completely relieved.

7. Resection of the injured segment of nerve will provide relief. Neurolysis and periarterial sympathectomy at the level of the injury are ineffective.

8. Sympathectomy should be done as soon as the diagnosis is established, to prevent the psychic trauma of prolonged pain and crippling joint stiffness.

9. Causalgia has been noted only with incomplete nerve lesions.

10. Recovery of function is often rapid after relief of pain. Consequently, primary neurorrhaphy is rarely indicated.

NOTE.—Our series of causalgia cases treated by sympathectomy now totals 105 cases as of December 31, 1945, including 2 additional cases of high sciatic injury requiring removal of the 11th and 12th dorsal ganglia, and the results and conclusions remain the same. For the same period 2,318 cases of peripheral nerve injuries were admitted.

TREATMENT OF PAINFUL SPONDYLOLISTHESIS

J. PUIG GURI, M.D.

SINCE the introduction of surgical procedures for the treatment of painful spondylolisthesis, one of the most frequent problems that the orthopedic surgeon has to face is to decide whether a specific case has to be treated conservatively or requires a spinal fusion. On the other hand, when this decision has been reached, and a spinal fusion is indicated, the next problem is in regard to the type of operative technique that will prove most satisfactory.

Some French surgeons oppose the use of the Albee technique on the basis that the graft is situated too far posteriorly (Guilleminet); that in the event of an associated spina bifida, it is impossible to obtain a solid insertion of the osseous transplant (Salmon and Contiades); or that when the superior spinal segment is markedly displaced, it is difficult to obtain good contact between the graft and the spinous processes (Mathieu and Demirleau). The technique preferred by most of these authors is the use of two flexible osteoperiosteal grafts placed on either side of the spinous processes. Desfosses and Colleu have advised the use of small grafts inserted between the superior and inferior articular processes, in order to obtain a bridging of the abnormal gap in the neural arch.

Because all these previously described techniques have no direct action upon the anterior part of the vertebra—where the real displacement takes place—several other procedures have been introduced directed toward producing a fusion between the vertebral bodies or the transverse processes of the fifth lumbar vertebra and the iliac bones, by means of an osseous transplant (Lance and Aurousseau, Friberg, Mathieu and Demirleau, Zahradnick). Others, following Capener's suggestion have been fusing the fifth lumbar body to the sacrum by means of a tibial graft placed through a transabdominal route (Burns, Jenkins, Kellogg Speed, Mercer, Friberg). Finally,

Dandy emphasizes the importance of the intervertebral disc pathology in cases of spondylolisthesis and advises the curettement of the defective disc or discs, and the fusion of the anterior spine.

In this clinic the surgical treatment of painful spondylolisthesis consisted of the use of the Hibbs' technique or a combination of those of Albee and Hibbs as described by Steindler. Technically both procedures have been safe and easily accomplished. However, they are not indicated unless there is assurance that the results obtained will be superior to results obtained by conservative treatment and that the procedures will prevent further slipping of the displaced vertebral bodies.

The purpose of this report is the review of the end-results of cases having a long term follow-up. The material available consisted of 313 cases of spondylolisthesis. For this analysis we selected those cases having good clinical and radiographic follow-up for at least 2 years after initiation of treatment. Cases with other extraspinal conditions that could mask the evaluation of the end-results (osteoarthritis of the hips, old fractures of femur or tibia, poliomyelitis of lowers) were also excluded.

There were 60 cases that fulfilled all these requirements. These patients were treated either conservatively or surgically or by a sequence of both. There were 45 males and 15 females. The age of the patients ranged from 12 to 55 years.

RESPONSE TO TREATMENT

Conservative measures. Thirty-four patients were treated by physiotherapy, traction, and spinal support. The results were as follows:

Complete relief, characterized by complete freedom from pain and ability to resume former occupation, was obtained in 14 cases (41.1%). In 1 of these cases back pain recurred after a symptom-free period of 10 years.

Partial relief, characterized by back pain only after exertion, was obtained in 12 cases (35.2%).

From the Department of Orthopedic Surgery, State University of Iowa, Iowa City, Dr. Arthur Steindler, Director.

No relief in 8 cases (23.5%).

Spinal fusion. These cases are divided in 2 categories:

1. Patients treated by fusion without previous trial of conservative treatment. In 26 cases spinal fusion was performed within a few weeks after the patient was admitted, or as soon as the acute episode of back pain had been relieved by physiotherapy and traction. The results were as follows: Complete relief, characterized by freedom from pain and ability not only to resume their former occupations but also their habitual sports, was obtained in 20 cases (76.9%). The observation period of these cases ranged from 2 to 8 years after operation was performed (average observation period was 3.5 years). Partial relief, characterized by some back pain after exertion, in 5 cases (19.2%). No relief in 1 case (3.8%).

2. Patients treated by fusion after trial with conservative treatment. In 13 cases of spondylolisthesis in which the conservative treatment had produced only partial relief or no relief at all, spinal fusion was ultimately performed. The results were as follows: Complete relief of symptoms was obtained in 7 cases (53.8%). These patients had been subjected to conservative treatment before the operation for periods of time ranging from 4 months to 5 years. The follow-up after spinal fusion was from 2 to 11 years (average observation period was 4.5 years). Partial relief of symptoms was obtained in 1 case (7.6%), the patient complaining of some back pain after exertion. Before operation this patient had continuous low back pain with sciatic radiation. No relief of symptoms was obtained in 5 cases (38.4%). These 5 patients were treated conservatively for periods ranging from 6 months to 1½ years, prior to surgery, with no improvement.

COMPARATIVE STATISTICS

If now we consider the results of the total 39 spinal fusions performed and compare with the 34 patients treated conservatively, we will observe that the percentage of good results was superior in the fused cases (69.2%) than in the ones treated by conservative measures (41.1%).

Also in favor of the surgical fusion, we must consider the fact that a certain number of the patients completely symptom free after the fusion of the posterior spine, had failed to respond adequately to conservative treatment.

THE PRESENCE OF SCIATIC RADIATION IN CASES OF SPONDYLOLISTHESIS

In 4 of the patients who failed to improve after surgical treatment, there was low back pain with associated sciatic radiation as far down as the ankle or toes. Since in recent years the rôle of the intervertebral disc as cause of low back pain has been greatly emphasized, these cases were rechecked for the possibility of overlooked disc pathology associated with the vertebral displacement.

The fact that these patients continued to complain of sciatic radiation after fusion was strongly in favor of this supposition. But it will be erroneous to form hasty conclusions based only on these 4 cases and state that the presence of a definite and persistent sciatic radiation before treatment constitutes a sign that all the symptoms will persist unless removal or curettage of the disc is performed.

Review of the histories of all the 60 patients here reported revealed the following:

Low back pain with sciatic radiation as far down as the ankle or toes was a complaint of 18 patients before initiation of treatment. In 10 of these cases, the radiation was unilateral; in the remaining 8, bilateral. In addition to the radiation, 3 patients complained of numbness and paresthesia in the lower extremities. The neurological examination was negative in all but 2, those being cases with unilateral radiation and having bilateral abolished Achilles reflex.

In none of them was the disc explored or curetted. They were treated either conservatively or by fusion of the posterior spine. Under treatment, complete relief of back pain and sciatic radiation was obtained in 10 cases (55.2%); complete relief of the sciatic radiation but some persistence of the back pain was obtained in 4 cases (22.2%); no relief was obtained in 4 cases (22.2%), which had previously been referred to as failures.

In view of these results, we have to accept either Steindler's proposal that there are other

conditions besides a herniated intervertebral disc that may produce sciatic radiation, or the fact that the symptoms produced by a defective disc when spondylolisthesis is present can be relieved in some cases by procedures other than the removal and curettage of the disc.

From a clinical point of view the most important point is the recognition of which patients will show improvement following fusion and which will remain unchanged after the surgical procedure has been performed.

Carefully checking the records of these 18 patients we were unable to find a definite sign. In all of them the neurological examination was inconclusive or negative; the leg signs were positive in both groups; so was the muscular spasm or the presence of sciatic scoliosis. However, there was one factor which appeared consistent and reliable. All patients who failed to respond to surgical fusion of the posterior spine were those who, under previous conservative treatment, had failed to show any degree of improvement. Consequently, it is advisable to treat these cases of spondylolisthesis with sciatic radiation conservatively for a period of time, and to perform an exploration of the intervertebral disc of those failing to respond, prior to fusing the posterior spine.

DEGENERATIVE CHANGES OF THE INTERVERTEBRAL DISC IN CASES OF SPONDYLOLISTHESIS

Degenerative changes in the intervertebral disc have been described by several authors. Schmorl and Junghanns found it deformed, thinner, sometimes S-shaped. Putschar observed the complete interruption of the annulus fibrosus and ossification of the anterior part. Hitchcock states that the buttress that develops on the anterior part of the sacrum in cases of spondylolisthesis is formed in large measure by the dislocation of the intervertebral disc itself.

As a result of this disc degeneration, instability and abnormal mobility at the level of the displaced vertebra are present. Roentgenographically, this is evidenced by the presence of sclerosis and reactive new bone formation.

In order to correct this instability, some surgeons have proposed fusing the anterior spine

at the level of the vertebral bodies. Dandy not only advises it, but states that fusion of the posterior spine without removing the discs accomplishes nothing because it merely covers the defective discs and the symptoms continue practically unchanged. Furthermore, he states that after the curettage of the disc the posterior graft will be contraindicated because it prolongs the period of recumbency and adds nothing to the fusion that follows complete removal of the disc.

We have no personal experience on this point but it seems to us that if all the symptoms described by the patient with spondylolisthesis could be relieved by fusing only the vertebral bodies, then one could conclude that in those cases in which spontaneous fusion between the fifth lumbar and the sacrum occurred, there should be freedom from all complaints. However, actual clinical experience does not substantiate this theoretical supposition. Among our material we found 3 cases in which there was an osseous fusion between the fifth lumbar body and the sacrum (Fig. 1), and 2 cases in which the osteophytic formation had been so marked that a solid osseous bridge extended all along the anterior part of the lumbosacral joint. Four of these patients were admitted complaining of recurrent episodes of low back pain of several years' duration. They were completely relieved either by spinal support or after a posterior spinal fusion had been performed.

These apparently contradictory findings cease to appear so paradoxical when, from the narrow field of the intervertebral disc, we turn to consider the vertebral column in its totality. It is then that we realize that in addition to the alterations produced by the defective disc upon the surrounding ligaments and nervous structures, the forward displacement of the whole upper spinal segment will also disturb the physiological harmony of the different structures responsible for the spinal stability and human posture. As a result, an extra burden is placed upon the spinal muscles and the spinal ligaments.

It is our impression that, while in cases of pure intervertebral disc disease or in very mild cases of spondylolisthesis the fusion of the anterior spine may be capable of produc-

ing a permanent relief, in those cases in which a marked forward displacement has already taken place, the posterior spine should be fused in order to provide a better stability for the back.

ROENTGENOGRAPHIC ASPECTS IN SPONDYLOLISTHESIS

The roentgenographic aspects of spondylolisthesis have already been described in detail by several authors (Schmorl and Junghanns, Capener, Brailsford) and consequently a general description is unnecessary. However, we are interested to study this condition through roentgenographic series of several years' duration, in order to determine the sequence of the pathological signs and to determine if there is any progression of the displacement after the conservative or surgical treatment had been undertaken.

One hundred and fifty-one cases were studied in detail. They were divided as follows:

Spondylolisthesis affecting the fifth lumbar vertebra. In 137 cases the displacement occurred at the fifth lumbar vertebra. Of these, 102 belonged to grade 1; 16 to grade 2; 10 to grade 3; 4 to grade 4, of Meyerding's classification. In addition, in 3 cases the displaced vertebra was inside the pelvis, in front of the first or second sacral segment.

Among the cases belonging to grade 1 of Meyerding's classification, the roentgenograms were not uniform. In 56 cases, the intervertebral disc was apparently normal. In 12 there was a thinning of the posterior part of the disc. In 34 the disc was markedly or totally destroyed. Sclerosis of the osseous surfaces could be observed in most of the cases with disc degeneration. In others, a buttress formation was present at the anterior part of the sacrum.

Among the cases belonging to grade 2 of Meyerding's classification, signs of localized osteoarthritis were present and practically all of them presented thinning of the intervertebral disc to variable degrees.

The cases belonging to grades 3 and 4 of Meyerding's classification could be subdivided in two groups, according to whether or not signs of new bone formation were present. When new bone formation took place, a buttress

at the anterior part of the sacrum was present in most of the cases, while in others the sacrum and the body of the fifth lumbar were fused together.

On the other hand when new bone formation did not take place, we observed the rounding off of the anterior border of the sacrum and, occasionally, the notching of the inferior surface of the fifth lumbar vertebra, forming what roentgenographically appeared to be a joint-like image between the last lumbar vertebra and the sacrum. The more advanced cases presented a tilting of the fifth lumbar body, a narrowing of the intervertebral foramen between the fourth and fifth lumbar vertebrae, and a flattening of the posterior third of the body of the last presacral segment (Fig. 2). Sclerosis of both osseous surfaces could be observed.

One of the most interesting phenomena was the flattening and redressement of the sacral body. In cases belonging to grades 1 and 2 of Meyerding's classification, the sacrum had a configuration and position compatible with anatomical individual variations. However, in some of the cases belonging to grade 3 and practically all those belonging to grade 4 of Meyerding's classification, on lateral projection the sacrum appeared to have a rounded off anterior border, the conformation was straight, and its position was more vertical than usual (Figs. 3 and 4).

Spondylolisthesis affecting the fourth lumbar vertebra. In 7 cases there was a forward displacement of the fourth lumbar vertebra. All presented a separate neural arch. The displacement was never very marked, corresponding to grades 1 or 2 of Meyerding's classification. In addition there was thinning of the intervertebral disc in 5 cases, localized osteoarthritis in 1 case, and sacralization of the fifth lumbar in 2 cases (Fig. 5).

Pseudospondylolisthesis of Junghanns. According to Sisefsky the term pseudospondylolisthesis was first used by Neugebauer for the cases of violent vertebral dislocation secondary to luxation fracture. More recently, Junghanns has used the same term to designate the dislocation of one vertebra upon another when there is not a preceding intense trauma or a separate neural arch. In addition, he observed

Fig. 5. Forward displacement of the fourth lumbar body. The fifth lumbar vertebra is sacralized.

More recently Stewart in a collection of Eskimo and Indian skeletons found 3 specimens similar to those described by Junghanns and could observe the existence of marked arthritic erosion of the articular facets of the small intervertebral articulations.

Among our patients we found only 1 case that presented all the characteristics described by Junghanns. The displacement occurred at the level of the fourth lumbar vertebra, and marked osteoarthritic changes of the opposing surfaces of the vertebral bodies were present. No signs of separate neural arch could be detected by lateral, right and left oblique projections. The corresponding intervertebral disc presented definite narrowing.

Reverse spondylolisthesis. The posterior displacement of a vertebral body has been observed by several authors and has received a wide variety of names. Sicard used the term retrospondylolisthesis; Lippens called it hierolisthesis; Mouchet spoke of sacrolisthesis; and finally the American authors (Ferguson, Smith, Johnson) have reported cases under the title of "posterior displacement of the fifth lumbar vertebra."

In spite of so many reports, the existence of such a condition has been denied by Willis, on the basis that we are dealing with an optical illusion. This author studied 50 skeletons of

the Haman Museum and found that in only 17 were the opposing surfaces of the fifth lumbar and the sacrum equal. Among the remaining ones, the anteroposterior diameter of the sacrum was from $\frac{1}{4}$ to 1 inch shorter than that of the opposing surface of the last lumbar vertebra. In addition, in some cases the posterior border of the sacral surface was concave toward the neural canal.

Among our cases studied, we found this condition in 5 cases. The displacement was minimal and affected the fifth lumbar vertebra in all cases. The anterior borders of the fifth lumbar and the sacrum were in alignment. The condition remained stationary.

As there was not a separate neural arch in any of our cases we prefer to use the term "posterior displacement of the fifth lumbar vertebra." In order to avoid confusion it will be advisable to use the term spondylolisthesis only in those cases in which the vertebral displacement is secondary to a separate neural arch.

Scoliosis associated with spondylolisthesis. In 5 cases of spondylolisthesis a lumbar scoliosis was present. The curve extended up to the first lumbar or twelfth dorsal vertebra. There were 1 male and 4 females. The ages ranged from 13 to 16 years when first seen in the clinic. The cases were observed from 2 to 5 years.

While this small number of cases does not allow generalizations, we may state that we observed two main types. On one hand, we had cases in which the rotation of the vertebral bodies was the main characteristic. In these cases the rotation was present several months before the lateral curvature appeared. Under treatment, the lateral deviation could be easily corrected by means of a plaster cast, but the rotation remained unchanged. On the other hand, there was another group of cases in which the lateral deviation was the outstanding phenomenon. When the patients were recumbent, the spine appeared roentgenographically essentially normal. In the standing position, the vertebral bodies presented a minimal amount of rotation. Two of the patients belonging to this group were able at will completely to straighten their spinal curvature.

Fig. 6. a and b. The only change that occurred between August 8, 1938, a, left, and December 14, 1944, b, was a thinning of the posterior part of the intervertebral disc. Fusion was carried out in December, 1939.

After spinal fusion, a straight but rotated spine was obtained in the cases belonging to the first group. A normal and painless spine was the end-result in the second group of cases provided that the spinal fusion had been performed during the early periods of the curvature.

The progression of the deformity. In cases of spondylolisthesis affecting the fifth lumbar body, it previously was a widely accepted fact that, except for cases in which a buttress or osseous synostosis was present, the forward slipping could progress at any time, thus increasing the deformity. This concept had been substantiated by reports of several authors who had followed the progressive slipping by serial roentgenograms.

Friberg in 1939 aroused the doubt that progression of the forward slipping was a constant or even frequent phenomenon after puberty. By repeated measurements of the roentgenograms of 142 patients treated conservatively, he was able to find a change in the position of the affected vertebra in only 10 cases. Seven of these patients were under 20 years of age. In all of them the displacement was minimal and could be explained on the basis of a degeneration of the intervertebral disc.

After completion of his study, Friberg concluded that if there was any slipping at all

during adult life, it never was to such a degree that would justify the use of dangerous operative procedures. He further stated that in the literature published after 1925 there was not a single convincing picture showing a spontaneous change in the affected vertebral body.

It should be remembered that Ferguson in 1934 had already stated that although a gradual slipping of the displaced vertebra without trauma could be possible, he had never observed a case. He stated also that the displacement did not have much, if any, tendency to increase.

Going over the literature of the past 10 years, we have found several descriptions of cases of progressive slipping reported by Brailsford, Watson-Jones, Ferguson, Burckhardt, Hitchcock. But at any rate the number was comparatively small.

In our material studied we had the opportunity to observe 35 patients for periods ranging from 2 to 7 years. After repeated x-ray films taken approximately every 3 to 6 months, we were unable to find progression of the displacement in any of them. Eleven of these patients had been treated conservatively; 24 of them had been treated by primary fusion or fusion was done after trials of conservative treatment (Fig. 6 a and b).

COMMENT

As spondylolisthesis is not a progressive condition after puberty in the majority of cases, the question arises as to when the displacement occurs.

It is an accepted fact that a marked forward displacement of the body of a vertebra, in the absence of trauma or pathological condition, is only possible because there is a separation at that part of the neural arch that Chandler called the "isthmus." The cause for the appearance of such a gap between the upper and lower articular apophysis of a vertebra has several theoretical explanations. One of the most widely accepted attributes the neural arch defect to a lack of fusion between two centers of ossification present in each half of a neural arch (Rambaud and Renault, Neugebauer). As more recent embryological studies have been unable to prove the existence of these two separate centers of ossification, and the percentage of spondylolysis found in human fetus is far lower than the percentage of separate neural arches observed in adult spines, this congenital theory has been less and less accepted. Other explanations, such as trauma at birth and after (Hitchcock, Azema, Glorieux and Roederer) progressive erosion of the isthmus, localized aseptic necrosis (Julitz), have been formulated by several authors.

Regardless of which of these theories we accept, the fact still remains that while spondylolysis may occur at any level of the spine, a marked forward displacement has only been observed at the fifth lumbar vertebra. This, together with the fact that while spondylolisthesis has been described in several human races it has never been found in the fetus or in the anthropoids (Willis), has called the attention of the anatomists and orthopedic surgeons to the peculiarities of the lumbosacral angle and to the characteristics of human posture.

The evolution of man's posture has been the object of several theoretical suppositions. Disregarding the more or less accepted explanations formulated by Keith, Morton and Wood Jones, we have fairly good evidence that man's posture, as an erect terrestrial biped, has suffered several modifications. Boule, in his book *Les*

hommes fossiles, states that the Neanderth man found in "La Chapelle aux Saints" had crouching posture, a minimal lordosis, and lower limbs were in slight flexion. On the other hand, Mitchell quotes the studies of Prof. Low, who, measuring the skeletons belonging to the Bronze age, found that the posterior vertical measurement of the lumbar vertebra slightly exceeded the anterior one. Prof. Turner reports on his studies on human skeletons during the "Challenger" expedition as widely known. He found that the lumbar spine of one of the most primitive forms of the human race, the Andaman Islanders, was almost straight or slightly convex backward. Finally, Cunningham, studying the skeletons of several human races from the collection in the British Museum and the Museum of the Royal College of Surgeons in England, found that there was a progressive diminution of the vertical diameter and an increase of the sagittal diameters in Europeans and natives of India as compared with more primitive races such as the Andamans, Australians and Negroes. This is interpreted as structural modification secondary to adoption of better posture, because the more erect a man is, the more weight a vertebral body has to carry.

Therefore, we see that the configuration of the human spine has progressively changed thus permitting more upright posture. However, the human spine has not only changed in configuration during the course of time. During the life span of an individual the vertebral column suffers also several alterations. These different changes have been described in detail by Bardeen, Willis, Carey, Mitchell and can be summarized as follows:

In an embryo of 7 millimeters the spinal column forms a single curve of forward convexity, the ventral surface of the sacrum facing the mid-thoracic region. From that moment on, there is a progressive uncoiling of the curvature. In an embryo of 50 millimeters the ventral surface of the sacrum faces approximately straight forward.

At birth, the lumbar spine is almost straight and the lumbosacral angle is minimal. Neither the vertebral bodies nor the discs are wedge-shaped.

When the child's hips start to extend, the lumbar vertebrae are pulled forward by the ligamentous structures and the psoas muscles, thus giving origin to the lumbar incurvation. This curve is fairly noticeable around the 6th to 12th postnatal month, when the child begins to stand and walk.

At the end of the second postnatal year a definite wedging of the lumbar vertebrae can be observed. Progressively, the sacral concavity becomes more and more marked and the lumbosacral angle more accentuated. The vertebral wedging increases until the subject reaches adult life.

In short, we may conclude that here we also observe the same phenomenon that took place during the course of ages: the apparition of a lumbosacral angle and of a lumbar lordosis in a previously straight or forward curved lumbosacral spine. The only difference is, that in an individual this process occurs from the time he is a 50 millimeter embryo up to puberty. If during this period a bilateral separate neural arch is present, the possibilities of a forward displacement should be very great. Especially at the level of the fifth lumbar vertebra, the point of connection between a movable and immovable spinal segment.

CONCLUSIONS

1. In cases of painful spondylolisthesis a complete relief of the symptoms was obtained in 41.1 per cent of the patients treated conservatively and in 69.2 per cent of the cases treated by spinal fusion.

2. In no instance was a definite progression of the deformity observed, after the treatment by means of braces or posterior spinal fusion had been undertaken.

3. Surgical procedures that endanger the life of the patient are not justified either from the view of the relief of symptoms, or in order to check the progression of the deformity.

4. The presence of a sciatic pain associated to the local spinal symptoms does not necessarily mean that permanent relief can not be obtained unless the disc is removed or cutted. In 55.5 per cent of the cases presenting such a clinical picture, complete relief was obtained either by conservative means or after the fusion of the posterior spine.

5. In advanced cases of spondylolisthesis the spontaneous fusion of the anterior spine after destruction of the intervertebral disc, did not constantly produce complete relief of the symptoms. On the other hand, following the application of a spinal support or the surgical fusion of the posterior spine, all the symptoms disappeared.

FUNCTIONAL RESTORATION OF THE THUMB

Pollicization of the Index

H. KELIKIAN, M.D., F.A.C.S., Chicago, Illinois, and E. W. BINTCLIFFE, M.S., F.R.C.S.

DURING the second World War we saw a number of injured hands with the thumb partially or completely ablated. The loss of the thumb deprives the hand of most of its usefulness. The palm can still be used as a paddle and the remaining fingers may serve as hooks. The fingers can by themselves curl around a bar, pluck a chord, scratch, press down, and pinch sideways. Without the thumb, the fingers cannot effectively hold a pen and wield it with skill and speed; the hand as a whole cannot grasp a tool and put it through efficient,

gainful work. Torque as used in turning a door knob or a screw driver becomes difficult; pulp-to-pulp pinch, or opposition, is lost.

Modern war missiles, especially high explosives, are extremely destructive. Their action is not selective. It is mangling, mixed. They destroy all the structures in their way, shatter the bones and tear the soft tissues into shreds. Not only the thumb is injured, but the other fingers, usually the index and its metacarpal, are involved. Infections of varying severity intervene and add their toll of destruction. It takes time and numerous co-ordinated attempts to salvage a thumb out of this havoc, or reconstruct one when it has already been amputated. It is, of course, desirable that the reconstructed thumb be

Fig. 1.

Fig. 2.

Figs. 1 and 2. The surgical anatomy of the ablated thumb with compound fracture of the second metacarpal bone of the hand as caused by gunshot.

Fig. 1. The vessels supplying the thumb and the radial side of the index arise mainly from the radial artery and its continuation, the deep palmar arch. The volar digital artery supplying the radial aspect of the index runs in a dorsal plane closer to the bone; it does not cross the corresponding digital nerve as does the artery on the ulnar aspect of the index (shown in the inset).

Fig. 2. A missile which tears the thumb off and shatters the second metacarpal bone of the hand often severs the volar digital artery which supplies the radial aspect of the index. The digital artery destined to supply the ulnar aspect of the index and emanating mainly from the superficial palmar arch is not involved. The preservation of this artery and its accompanying nerve constitutes the crux of the problem.

Fig. 5.

Fig. 6.

Fig. 6. Volar incision is deepened by severing the transverse fibers of the palmar aponeurosis. The artery which is destined to supply the radial aspect of the long finger is ligated and cut beyond the bifurcation of the mother trunk. The digital nerves are left undisturbed. The deep or transverse metacarpal ligament is cut, volar and dorsal incisions are joined. Index finger is abducted from the remaining fingers.

painless. It must move in and out of oppositional position: abduct, flex and touch the other finger tips. It must feel or at least distinguish between hot and cold and convey some awareness of shape and position. In many cases that came to our attention primary wound excisions had already been per-

formed in other stations and we often did not know how conserving, yet complete, the initial surgery had been. Military exigencies forced us in turn to evacuate soldiers whom we had begun treating. The follow-up was difficult. We did, however, carry on the work on a number of injured thumbs and complet-

Fig. 13. The coned end of the metacarpal of the index is levered into the cavity of the multangular bone. Wire suture is passed to hold the two bones together. The long abductor of the thumb is anchored to the metacarpal of the index. (This part not shown.)

ed the job of reconstruction. It is hoped that a survey of what was done—of the various steps taken—in transferring the index finger to take the place of the missing thumb would not be amiss.

Two representative cases are here essayed.¹ In one the thumb had been disarticulated completely at the carpometacarpal junction and the second metacarpal bone of the hand was fractured at its base; in the other the thumb was disjunctured through the metacarpophalangeal joint and the distal end of the second metacarpal bone had suffered a compound fracture. Both patients were seen by us within 10 days of the original gunshot injury. They were sent to us with the damaged hand enclosed in circular plaster cast. Upon removal of the latter, further examination revealed that in addition to the missing thumb, the second metacarpal bone of the hand had suffered a compound comminuted fracture; the extensor tendons of the index finger were severed but the flexors functioned; finally, the sensibility of the index finger was dulled along its radial aspect but remained intact on the ulnar side. From these findings and from the extent of the wound, it seemed safe to surmise

that the artery emanating from the deep volar arch and destined to supply the radial side of the index finger was probably severed; a similar fate perhaps betook the smaller dorsal twigs which accompany the digital branches

of the radial nerve part-way into the index finger; the only sizable blood vessel that maintained the circulation of the damaged index was the volar digital artery which runs along its ulnar aspect; the nerve which accompanies this artery, a branch of the median, constituted the sole pathway of sensation (Figs. 1 and 2). *The preservation of this artery and nerve became our primary concern in trying to pollicize the index finger.* The principles of asepsis, chemotherapy, wound closure, prevention of contractures, immobilization and elevation and functional exercises were also adhered. The entire management resolved itself into a pattern which will be described as it was applied for the case with more radical ablation of the thumb: that with disarticulation at the carpometacarpal junction (Figs. 3 to 18). The management was altered slightly, curtailed and short-circuited, for the case with disarticulation of the thumb through the metacarpophalangeal joint.

THE PATTERN OF MANAGEMENT

1. *Examination and appraisal.* The original cast is removed, the wound inspected; the sensation of the index finger and its power to be actively flexed are tested; an x-ray picture of the entire hand is taken. The hand and forearm are then thoroughly washed with soap

and water, wrapped in sterile dressings, splinted and elevated.

2. *Preparation of a pedicled tube (or flap) and revision of the wound of the hand.* The following day, with the patient under general anesthesia, a tube graft (a flap in the milder case) is raised from an appropriate area of the abdomen. The hand wound is then revised all necrotic tissue, foreign particles, detached pieces of bone and blood clot being removed. Hemostasis is procured. The wound is covered with a fine mesh gauze; the hand and the forearm are encased in a skin-slug, well molded cast, the fingers being left free.

A banjo-splint is incorporated in the cast and elastic finger-nail traction is instituted. The limb is elevated. The traction is maintained at night to prevent contracture of the fingers; during wakeful hours it is released and the patient is coaxed actively to flex and extend all undamaged fingers, to flex the index finger against resistance.

3. *Deepening the web-space between the index and long fingers.* When it is made certain (usually about 4 weeks) that the abdominal tube would obtain sufficient blood from its root farthest away from the damaged hand, the other end is lifted with a sizable flap of skin, bearing a thick pad of fat. Under safe and adequate constriction of the arm (blood pressure

Fig. 19. Roentgenogram of the hand soon after gunshot injury, before wound excision.

Fig. 20. Roentgenogram of the hand following wound excision.

Fig. 21. Roentgenogram of the hand showing osteosynthesis of the proximal phalanx of the index to the metacarpal of the thumb which was performed at the same time as closure of the hand wound, deepening of the intermetacarpal cleft and covering this with a freshly raised abdominal flap.

cuff) the web space between the index and long fingers is deepened to about 3 centimeters proximally. The skin incision begins over the dorsum of the hand, in the cleft between the second and third metacarpal bones: It is deepened sufficiently to reveal the band connecting the extensor tendons of the index and long fingers. This *junctura tendinum* is sharply cut through. The incision is then carried across the interdigital web to the volar surface where it runs proximally, past the distal crease of the palm and then curves ulnarward. The volar incision is deepened cutting through the transverse, interlacing fibers of the palmar aponeurosis. The common arterial trunk which bifurcates into digital vessels for the adjacent sides of the index and long fingers is definitely identified. The digital nerves diverge from their trunk more proximally behind the artery: They are left unmolested. The digital artery going to the radial side of the long finger is carefully isolated. It is doubly ligated well beyond the bifurcation of the common trunk and cut between the two lig-

atures. The deep or transverse metacarpal ligament which binds the adjacent metacarpal heads firmly together is then sought and severed. The distal fragment of the fractured second metacarpal bone, thus freed, can now be abducted radially with the index finger revealing a deep cleft. The latter is bounded on its radial side by the fractured second metacarpal bone and the first volar interosseous muscle; the second dorsal interosseous, the third metacarpal bone and second lumbrical remain on the ulnar aspect of the deepened cleft. The arm constriction is removed (blood pressure cuff is deflated) and all bleeding points are caught and ligated. The deepened web space is covered with the flap of skin at the detached end of the abdominal tube. A catheter, made rigid by passing a Kirschner wire, is sutured to the finger nails of the abducted index and of the long fingers and this spreader-splint is bound to the torso by adhesive tape. Functional exercises are continued. In addition to finger exercises the forearm and elbow are lifted from the belly repeated-

Fig. 22. The hand wound 1 week after it had been castrated and elevated—2 weeks after the gunshot injury—and immediately before surgery. Note that wound extends dorsally cutting across the extensor tendons of the index and overlying sensory nerves; it passes radially across the pathway of the artery and nerve destined to supply the radial aspect of the index finger; the flexor tendons which pursue an oblique course along the ulnar side of the wound were not disturbed.

Fig. 23. Abdominal flap is sutured to the deepened intermetacarpal cleft; the primary wound is closed; finger-nail spreader-splint is anchored to the torso.

Fig. 24. The hand is released from the abdomen and the detached flap is made to replace the scar-bound skin in the region of the distal palm.

ly so as to obviate flexion deformity of the wrist.

4. *Release of the hand from the abdomen; covering the original wound; removal of scar-bound skin and its replacement with padded integument.* After it has been definitely made certain that the tube graft receives sufficient blood from the end attached to the hand—after 5 to 6 weeks from the preceding proce-

dures—the other end of the tube graft is detached from the abdomen. The original wound of the hand is refreshed; excess granulation and scar-bound skin is excised; hemostasis is procured. The pedicled tube, anchored into the deepened and widened interdigital web space, is slit open. It is trimmed

until its cut margins definitely bleed and what is fashioned out of it is made to cover the refreshed hand wound. The limb is then encased in a snug circular cast with the fingers left free. It is elevated. Finger exercises are insisted upon.

5. *Osteosynthesis and rotation of the index finger into a position of opposition.* Another 6 weeks are allowed to lapse. By then the distal fragment of the fractured second metacarpal bone has affected a faulty union. Through a dorsal incision, avoiding the previously placed skin grafts, the second metacarpal bone of the hand is osteotomized at about the level of malunion. The incision is extended to the back of the wrist and to its radial border. The severed tendon of the long abductor of the thumb is now sought and secured with the holding suture. The distal surface of the greater multangular bone is exposed and excavated; the proximal end of the distal fragment of the osteotomized second metacarpal bone is coned and inserted into the cavity already gouged in the greater multangular bone. The two bones are transfixed together with a malleable wire suture. The dissected end of the abductor pollicis longus is anchored to the now transposed distal fragment of the second metacarpal bone. The incision is closed, a Kirschner wire is passed through the distal phalanx of the abducted index and cut short. It is connected to a special rotation splint incorporated in the cast. During the ensuing 2 weeks, before hard callus could deposit, the transposed index finger is gradually rotated in a clockwise direction until it comes to face the long, or preferably the ring, finger. It is then held immobilized in an adequate cast so that all undamaged fingers and the distal

joint of the new pollex are left free for exercise.

6. *Functional recovery.* Immobilization is persisted in until firm union has taken place between the two bones: the metacarpal of the index and the greater multangular of the wrist. After the removal of the final cast the patient is coaxed to carry on such co-ordinated useful exercises as holding a pen, a fork, a card. He is encouraged to practice pressing down on a keyboard, grasping a tool and feeding himself. These small feats are easily attained when functional exercises had been carried on throughout the entire management—without the benefit of any special course of re-education.

VARIATIONS AND SHORT-CUTS

While the web space is being widened and deepened, it would have been feasible to have temporarily covered the original wound of the hand with a free split thickness graft. In a case to be reported elsewhere, we raised a separate flap for the hand wound at the time one was anchored to the deepened web space. In the case with disarticulation of the thumb at the metacarpophalangeal joint (Figs. 19 to 32) the edges of the gunshot wound were refreshed and sutured together. At the same sitting the web space between the index and long fingers was deepened; the proximal end of the first phalanx of the index and the distal end of the metacarpal of the thumb were divested of their articular cartilages, apposed, and transfixed together with a wire suture; the deepened web space was covered with a freshly raised abdominal flap and spreader-splint was sutured to the finger nails. After 5 weeks the hand was disconnected from the abdomen and the remnants of the skin flap was utilized to

replace the scar-bound skin on the palm; a short Kirschner wire was passed through the distal phalanx of the transposed index and connected to the rotation splint. When the desired position was attained the rotation splint was replaced by a regular plaster cast immobilizing the new pollex and permitting functional exercises.

COMMENT

The management described has enabled us successfully to transfer the damaged index finger to take the place of the missing thumb. It is to be noted that the cases here assayed presented relatively fresh wounds and compound fractures—wounds caused by gunshot—gaping wounds that were potentially infect-

ed. To what extent did chemotherapy contribute to this success would be difficult to say. We did administer sulfa drugs and penicillin in usual doses early in the treatment of wounds and for a few days after each major surgical undertaking. But we relied more on surgical care; on avoidance of added damages; on time and proper splintage to promote healing of the injured structures, and on time alone to enhance adequate vascularization of skin grafts. For the case with complete ablation of the thumb, the management was spread over a period of 7 months. The case with disarticulation at the metacarpophalangeal joint took only 4 months. Long lapses of time did not seem as important as restoring these wounded hands to functional usefulness.

LOBECTOMY AND PNEUMONECTOMY IN THE TREATMENT OF PULMONARY TUBERCULOSIS

SUFFICIENT experience has been accumulated in the past five or six years to make it possible to predict the place that lobectomy and pneumonectomy are likely to have in the surgical treatment of pulmonary tuberculosis. That it would never be possible to excise all of the tuberculous disease in any patient has been obvious from the beginning. Most surgeons have been surprised in the course of their experience by the fact that the disease is frequently found to be more extensive when the chest is opened than the x-ray had led them to believe. Lobectomy or pneumonectomy is not a substitute for any of the forms of collapse therapy and where one of these procedures is likely to prove effective it should be employed in preference to excision. On the other hand, it must be recognized that there are lesions that are unlikely to be con-

trolled by any of the older methods. To state that thoracoplasty is effective in 90 per cent of cases and carries a low mortality is not an argument against lobectomy or pneumonectomy. It is with the types of cases in which thoracoplasty has proved unsatisfactory that the results of the more radical forms of treatment should be compared.

Patients with well marked bronchial stenosis, particularly if repeated febrile attacks occur or if the sputum continues positive in the involved area, should be submitted to lobectomy or pneumonectomy provided the disease in the remainder of the lung is healed or sufficiently quiescent. The operation should not be undertaken if it will necessitate the division of the bronchus through a site of active disease. Areas of tuberculous bronchiectasis which continue a source of positive sputum should be excised. Hemorrhage from such areas in the lower or middle lobes and usually in the upper lobe should be considered an indication for excision, although in the upper lobes thoracoplasty may be the procedure of choice. Atelectatic lobes or portions of lobes which remain the only source of tubercle bacilli should be removed since no other treatment is effective. Cavities which remain open in the presence of what should be an effective pneumothorax ought to be treated by lobectomy if the condition of the remainder of the lung will permit it. In the case of upper lobe cavities of this type it is sometimes wise to do a preliminary thoracoplasty and face the fact that should the sputum remain positive it may be necessary to do a secondary lobectomy. Lobectomy is also indicated in tuberculosis confined to a lower or middle lobe when because of adhesions the disease is not con-

trolled by pneumothorax or phreniclasia. Solitary large tuberculomas should, as a rule, be removed. Such lesions, whether or not collapse therapy has been employed, are prone to undergo necrosis sooner or later, and not infrequently cause dissemination of the disease. That dissemination occurs occasionally in spite of lobectomy is not a valid argument against the procedure, since it will almost certainly happen much less frequently than with any other form of treatment. Massive tuberculous disease in one lung when the lung on the other side is in good condition may occasionally be an indication for pneumonectomy, but this is a doubtful indication and the percentage of satisfactory results is likely to be disappointing.

The long term results of these procedures, as in other forms of surgical treatment, are certain to be influenced by the postoperative management. Prolonged rest is indicated for all cases, particularly if there has been evidence of activation of apparently quiescent

pre-existing lesions. Although activity may be permitted fairly early following excision of certain unusually localized foci of disease the management should in general be much the same as though the patient had had a thoracoplasty. Many patients continue to have positive cultures from sputum or gastric lavage for some months following operation. In many such patients the source of the positive sputum is not apparent.

Lobectomy and pneumonectomy undoubtedly have a place, although a limited one, in the surgical management of tuberculosis. Too much enthusiasm unquestionably has resulted in the employment of these procedures in unsuitable cases. Fortunately it is in those cases in which the indication is most obvious that the results are most satisfactory. Lobectomy and pneumonectomy represent additions to the many forms of surgical care of tuberculosis, and time and experience alone will determine the lesions for which they are most suitable.

ROBERT M. JAMES.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

IN his book entitled *Pneumoperitoneum Treatment*¹, Dr. Banyai has presented the subject so thoroughly that it should no longer be considered a therapeutic fad. Although a voluminous literature has been published on various phases of the subject, this is the first comprehensive monograph. The author, a pioneer himself in the use of pneumoperitoneum, recapitulates the literature and reports on his own experience.

After giving the history of the development of pneumoperitoneum treatment, he devotes a considerable amount of space to discussing the technique. However, it was difficult to decide which of the various methods described was the one of choice.

A very complete discussion of the physical and physiological changes produced by pneumoperitoneum, and of the complications encountered in its therapeutic use, furnishes the background for the clinical application of the procedure.

As the author presents the various diseases and pathological conditions for which pneumoperitoneum has been used, he discusses the fundamental processes involved and the apparent manner in which the pneumoperitoneum works.

Pneumoperitoneum has been used for a long time in the treatment of tuberculous peritonitis and enterocolitis and in general has been effective. The types of the disease suitable for it are clearly described.

Its use in the treatment of pulmonary tuberculosis has been the subject of the greatest amount of discussion and of heated differences of opinion. The largest section of the book is devoted to this field and the author summarizes the extensive literature and draws on his own large experience to formulate his conclusions. That pneumoperitoneum is of value in the treatment of certain cases has been established and that it should not be used to the exclusion of all other forms of treatment is a statement that all will accept. As a result of this chapter alone, Dr. Banyai should succeed in convincing everyone that pneumoperitoneum is a method of treatment which should be a part of the armamentarium of everyone treating pulmonary tuberculosis.

Although most physicians are familiar with the use of pneumoperitoneum in the treatment of pulmonary tuberculosis, few realize that it has also been used quite extensively in the treatment of a wide variety of other chest conditions. These other indications for its use are discussed thoroughly, and a clear presentation of the pathological state in each

instance is followed by a summary of the results to be expected and of those obtained. Of particular interest is the discussion of the use of pneumoperitoneum in certain cases of bronchial asthma and of pulmonary emphysema.

In this book Dr. Banyai has succeeded in presenting a very controversial subject in a well balanced and comprehensive manner. No longer should pneumoperitoneum be considered a therapeutic fad. Although the book would be improved by a more complete digest and arrangement of the literature and by the routine use of a summary at the end of each chapter, it is recommended to everyone interested in the treatment of chest disease.

RICHARD H. MEADE, JR.

THE second edition of Saphir's *Autopsy Diagnosis and Technic*² hews to the line in its purpose of providing a handbook of autopsy technic and morbid anatomy for the student. The general practitioner and the general pathologist are not beyond the realm of its usefulness. There are 375 pages divided into 26 chapters. Sixty-nine illustrations and 18 tables are helpful accompaniments of the subject matter.

The reviewer heartily endorses the author's idea of the protocol, in Chapter II, page 25. "Too often, autopsy protocols are so packed with irrelevant detail that the reader has difficulty in his attempt to glean the pertinent data from the maze of words offered by the writer."

Religious prejudices to examination of the body after death are adequately disposed of, at least in theory. Unexpected death from natural causes and notes on accidental death are given excellent coverage for the space allotted. The general necropsy technic is treated in a methodical and cogent style.

The student will find the various tables on the differential diagnosis of the morbid processes affecting the major organs of extreme value. Rich's table on the pathogenesis of forms of jaundice has been incorporated to aid the student in the modern interpretation of jaundice, its pathogenesis and concomitant morbid changes. Special attention also has been given to neonatal pathology.

Additions to the text in the second edition are the anatomic changes found in association with certain vitamin deficiencies and tropical diseases. This compact manual well serves its purpose within the limits of its scope.

EUSTACE L. BENJAMIN.

¹*PNEUMOPERITONEUM TREATMENT*. By Andrew Ladislaus Banyai, M.D., F.A.C.P., F.C.C.P. St. Louis: The C. V. Mosby Co., 1946.

²*AUTOPSY DIAGNOSIS AND TECHNIC*. By Otto Saphir, M.D. With a foreword by Ludwig Heikton, M.D. 2d rev. ed. New York: Paul B. Hoeber, Inc., 1946.

THE book by Collens and Boas entitled *The Modern Treatment of Diabetes Mellitus*¹ was designed as a practical, comprehensive guide for the general practitioner who treats diabetic patients, and particularly for those who have not available the services of a competent dietician. The principles underlying the selection of a suitable dietary formula are explained. The formula decided, the physician (or the patient) can translate it into a menu by copying from the diet calculator supplied with the book. This calculator, about which the chapters on feeding are built, has the merit of simplicity and is one method of prescribing meals with accuracy if not always in good balance or to the satisfaction of the patient. There seems little question but that a trained dietician can serve the individual patient better and without the need of a calculator at her elbow. Included are chapters on the technique of insulin administration and urine examination, which might well be printed in pamphlet form for the use of the patient.

This book has great value in presenting in clear and readable form material that is seldom presented simply. The procedures of the authors, based on large clinical experience, are definite and logical even as regards controversial details and are, therefore, bound to be helpful to the reader. Commendable, and in line with modern practice, is their emphasis on the efficacy of measured rather than weighed quantitative diets, their emphasis on simplifying instruction, and their selection of formulas that approach as nearly as possible the normal diet.

Clinical differentiation as regards treatment includes the following types: mild diabetes in individuals who are obese, undernourished, and of normal weight; diabetes of moderate severity; and severe diabetes without ketosis, with ketosis, and with uncompensated ketosis. Short chapters on diabetes in children and in pregnancy are included. The chapter on the history of the disease is excellent. The associated degenerative arterial changes of diabetes receive extensive discussion; those of the peripheral arteries are presented at such length that the subject of their treatment merits mention on the title page. The authors have achieved the aims set forth in the preface of their book. Students and physicians will profit by reading and studying it.

WALTER H. NADLER.

THE previous volumes by Saegesser on surgical operative technique and infections of the hand have already served to introduce this Swiss surgeon to the American profession. For many years first assistant to de Quervain, Saegesser has been brought up in the best of European surgical tradition in training and clinical experience. As teacher of clinical surgery with particular interest in the practical problems of surgical technique and therapeutics Saegesser presents his material clearly, methodically, and logi-

cally. *Spezielle Chirurgische Therapie für Studierende und Ärzte*² is distinctly more than a book on operative technique. He has noted in the preface the questions he wishes to answer: first, what to do in a certain situation; and, second, how best to do it. These questions he has tried to answer "in simple and understandable fashion . . . without learned frills . . . with the idea that in this way the value of the book would not suffer but rather would be increased."

The volume covers the entire field of general surgery omitting brain tumors, plastic surgery, eye, ear, nose and throat surgery, but it does include sizable chapters on urologic surgery, surgery of the bones and joints including maxillofacial fractures, and compression fractures of the spine as well as a special chapter on cord compression. While this is essentially a treatise on therapy and operative indications and technique, many topics considered are accompanied by succinct discussions of diagnosis, differential diagnosis, preoperative and postoperative care, and gross pathology. In the 270 pages devoted to abdominal surgery, for example, one is very much impressed by the space devoted to preparation of the patient for operation and the discussion of methods for preventing and managing complications post-operatively. The book presents those procedures which Saegesser has found best, for while he admits there are often many ways of doing things in surgery one method is usually the best. The reader is not confused with a wide choice of procedures but is presented with a logical uniform approach to surgery.

There are several places where Saegesser's practice and current American practice differ. One is struck by the absence of reference to preparation in large bowel surgery with the sulfonamides; water and electrolyte balance, protein metabolism and vitamin administration are not stressed as they would be in current American texts. The use of suction in abdominal surgery does not seem to be as much appreciated in Switzerland as it is here. The chapter on burns is quite sketchy and seems particularly incomplete in view of British and American contributions in the past ten years.

These criticisms, however, are of minor significance when the volume is considered as a whole. The subject matter is presented in the fashion such as only a trained teacher can present it and the book will serve as a standard for many years. The nearly two thousand line drawing illustrations are excellently done and add greatly to the value of the text. The volume is well worth reading by the student, the general surgeon, and especially by the teacher of surgery.

MICHAEL L. MASOV.

THE small volume *Human Torulosis*³ by Leonard B. Cox and Jean C. Tolhurst is a concentrated treatise on the historical, clinical, and experimental aspects of the Torula histolytica. The authors point

¹THE MODERN TREATMENT OF DIABETES MELLITUS; INCLUDING PRACTICAL PROCEDURES AND PRECAUTIONARY MEASURES. By William S. Collens, B.S., M.D., and Louis C. Boas, A.B., M.D. Springfield, Illinois: Charles C. Thomas, 1946.

²SPEZIELLE CHIRURGISCHE THERAPIE FÜR STUDIERENDE UND ÄRZTE. By Max Saegesser. Bern: Hans Huber, 1946.
³HUMAN TORULOSIS. By Leonard B. Cox, M.D., and Jean C. Tolhurst, M.Sc. Melbourne: Melbourne University Press, 1946.

out that the cases of infestation of the human body by torula are unquestionably much more common than they are usually supposed to be. Over a hundred cases have been reported (the greatest number being from the United States), and no doubt the disease is still considered rare—which it should no longer be—simply because it is not recognized. No doubt many patients with "tuberculous meningitis" actually have a torular infestation.

The authors present the detailed case histories of 13 patients of their own who suffered from this disease, and from their own series as well as from a comprehensive review of all available reported cases by other authors, show that the central nervous system is the most commonly affected of all the systems of the body and that death most frequently is from that cause. The lung is the next most commonly involved organ, but actually the yeast-like organism may invade and destroy almost any tissue or organ in the body. The most likely portal of entry, they believe, is through the respiratory tract. The common source of the organism is not completely known, though it is to be found in many soils, and it may even be air borne. Neither is it understood how it may pass from individual to individual, if indeed it may. Within the body the torula may pass through the blood or lymph streams, circulate throughout the cerebrospinal fluid system and thence into the perivascular spaces, or it may pass directly into tissues contiguous with a focus. Torulosis in experimental animals closely resembles the human disease in the matter of locus of lesions in the organs of predilection and in the time element of lesion development.

At present there is no known effective treatment for torular infestation. The drugs of the sulfa group are ineffective, as is penicillin. The salts of some of the heavy metals have been used without result. Some lesions of the lungs apparently heal spontaneously; surgical excision or drainage seems to help effect a cure where such treatment is possible; infestation of the central nervous system is fatal. Many excellent illustrations of the organism and of typical organ lesions are furnished, and as are directions on differential staining of the torula.

JOHN MARTIN.

THE latest member of the series of *General Practice Manuals* is a compact volume¹ designed as an aid to the medical student, the part time anesthetist, and others who may be called upon to employ depressant drugs, alleviate respiratory depression or obstruction, and treat hypoxia or shock. The presentation, therefore, is confined to fundamental and practical considerations of anesthesiology.

In the chapter on preanesthetic medications, a useful table lists the recommended dosage of the various drugs and combinations of drugs for the average patient of the difficult age groups. A particularly timely section is that dealing with the rational treatment of severe drug depression.

¹ANESTHESIA IN GENERAL PRACTICE. By Stuart C. Collen, M.D. Chicago: The Year Book Publishers, Inc., 1946.

No other single factor is as essential to a safe and satisfactory anesthesia as the establishment and maintenance of a perfect airway, and this point has been stressed, as have the undesirable effects resulting from an inadequate airway. Following is a discussion of the common sites of respiratory obstruction and the symptoms of this condition and their alleviation.

The pharmacology of curare and the technique of its use as an adjunct to inhalation anesthesia is presented in some detail. This is a procedure in which the author has pioneered and he is well qualified to speak with authority on this subject.

The four pages of cartoons regarding the correct and incorrect management of toxic reactions of local drugs are clever and instructive.

A number of relatively simple nerve blocks which serve a useful purpose in general practice are presented in some detail. Table 2 shows in graphic form the essential properties of the drugs used for nerve block and spinal anesthesia.

Moon's valuable diagram of precipitating and perpetuating factors in secondary shock and a chart of physiopathologic changes during the development of shock are useful inclusions in the chapter on the recognition and treatment of shock.

It is emphasized that the recognition of incipient hypoxia and the prompt institution of oxygen therapy are essential factors in the securing of good results. The signs of oxygen want, types of hypoxia, and the physiology of oxygen transport are outlined. The methods of administration of oxygen are illustrated.

An appendix deals, in outline form, with the anesthetic agents available for office use.

The author has achieved his purpose in a clear, concise presentation of the material in this text. No new or controversial concepts have been included, but a comprehensive and instructive manual has been prepared. The volume is well arranged, of attractive format on good stock. It will be of value not only to the student, but to the teacher as well.

MARY POE.

THE book *Urologic Roentgenology* by Miley B. Wesson² is an authoritative volume by an outstanding urologist of brilliant scientific background and long clinical experience. The author has drawn upon his own large material as well as that of many others to produce a very fine series of representative roentgenograms which are reproduced with remarkable detail and texture.

The numerous illustrations are an atlas in themselves and in the relatively brief accompanying text the subject of urography is very completely covered. Intravenous as well as retrograde urography is discussed at length, including the indications, technique, and complications.

With the widespread use of intravenous urography too much reliance has been placed upon this procedure alone for diagnosis. The author, therefore,

²UROLOGIC ROENTGENOLOGY. By Miley B. Wesson, M.D. and rev. ed. Philadelphia: Lea & Febiger, 1946.

stresses the need for complete urinary tract studies including retrograde urography to confirm findings.

The technique of interpretation is described at length and the diagnosis is not considered empirically but the underlying pathology and the mechanism of the pyelographic changes are presented.

The material which could well have occupied a much larger volume has been condensed to 252

pages; but thanks to careful editing and skillful writing, it makes for easy and pleasant reading. The chapter on congenital anomalies is especially well presented.

This book, which is intended mainly as a guide for the beginner, can be recommended as well to the experienced urologist, for it contains much practical information.

PRELIMINARY PROGRAM FOR THE 1946 CLINICAL CONGRESS IN CLEVELAND—DECEMBER 16 TO 20

THE five-day Clinical Congress of the American College of Surgeons will open in Cleveland on Monday morning, December 16, at 9:30 o'clock. Headquarters will be in the Cleveland Public Auditorium, and the Statler and Cleveland hotels, with most of the sessions, except the clinics at the hospitals, being held in the Auditorium. Outlines of the programs appear on following pages. They show an interesting and varied plan of presenting wartime and postwar developments in surgery through the media of operative and nonoperative clinics, demonstrations, symposia, panel discussions, forums, motion pictures, and exhibits.

The program of the Congress will include the twenty-fifth annual Hospital Standardization Conference, which will convene during the first four days, with morning and afternoon sessions on Monday through Thursday beginning at 9:30 o'clock and 2:00 o'clock, respectively, and evening meetings on Tuesday and Wednesday beginning at 7:30. Breakfast conferences are also scheduled on Wednesday and Thursday mornings.

The first event on the Clinical Congress program will be the General Assembly for surgeons and hospital representatives which will be held on Monday morning. The Monday afternoon program will include two panel discussions, one beginning at 1:30, the other at 3:30; clinics in the local hospitals; a hospital conference; and a surgical film exhibition. The Monday evening program will be devoted to the Presidential Meeting.

On the four mornings beginning Tuesday at 8:00 o'clock, operative and nonoperative clinics

will be held in the local hospitals. From 9:00 to 12:30 on each of these mornings, the Forum on Fundamental Surgical Problems will meet in two sections—one section in the Music Hall and the other in the Ballroom of the Cleveland Public Auditorium. From 9:30 to 12:30, Tuesday through Thursday, hospital conferences will be held in Club Room B of the Auditorium. From 9:30 to 11:00 o'clock on Tuesday through Friday, surgical film exhibitions are scheduled on ophthalmology and otorhinolaryngology and from 10:00 to 12:00 o'clock on general surgery. At 11:00 o'clock on Tuesday through Thursday, panel discussions on ophthalmology and otorhinolaryngology will be held.

Afternoon programs each day include clinics; two major panel discussions from 1:30 to 3:00 and from 3:30 to 5:00 o'clock respectively (except Thursday when only the 3:30 panel will be held); hospital conferences (Monday through Thursday); and surgical film exhibitions. In addition, on Tuesday afternoon at 2:00 o'clock there will be a symposium on fractures and other traumas; on Wednesday afternoon at 2:00 o'clock a symposium on cancer; on Thursday afternoon at 3:00 o'clock a panel discussion on graduate training in surgery; and on Friday afternoon six concurrent specialty panels from 2:00 to 5:00 o'clock in the fields of obstetrics, plastic surgery, neurological surgery, thoracic surgery, urology, and orthopedic surgery.

Symposia on general surgery will be held on Tuesday, Wednesday, and Thursday evenings; symposia on ophthalmology and on otorhinolaryngology on Tuesday and Thursday evenings; and

a symposium on plastic surgery of the head and neck on Wednesday evening. The concluding event of the Clinical Congress will be the Convocation to be held on Friday evening at 8:15 o'clock in the Music Hall of the Cleveland Public Auditorium.

CLINICAL PROGRAM

With the aid of a representative in each hospital, a committee on arrangements appointed by the surgeons of Cleveland, with Dr. Thomas E. Jones as chairman and Dr. John W. Holloway as secretary, has prepared a preliminary program which is published in succeeding pages. This consists of operative and nonoperative clinics, demonstrations, presentation of cases, symposia, pathological conferences, and surgical staff conferences.

Eighteen hospitals are listed in this preliminary outline, and the program for each hospital is classified according to specialties. A wide range of subjects is covered, including general surgery, pathology, fractures and other traumas, thoracic surgery, tumor surgery, plastic surgery, ophthalmology, otolaryngology, neurosurgery, vascular surgery, orthopedic surgery, obstetrics and gynecology, genitourinary surgery, oral surgery, and roentgenology.

The clinics and demonstrations will be held in the hospitals every morning and afternoon beginning Tuesday, December 17.

A complete detailed clinical program for each day will be posted in the form of bulletins at headquarters in the Cleveland Public Auditorium during the afternoon of the preceding day and the program will be distributed in printed form each morning.

GENERAL ASSEMBLY

The Clinical Congress will open with a general assembly in the Music Hall of the Cleveland Public Auditorium at 9:30 o'clock on Monday morning. Dr. W. Edward Gallie, President of the College, will preside at this meeting which will be the opening session of the twenty-fifth annual Hospital Standardization Conference. Dr. Irvin Abell, Chairman of the Board of Regents, will report on the progress of the 1946 Hospital Standardization survey, final results of which, including the Approved Lists of hospitals, cancer clinics, and approved hospitals for graduate training in surgery, will be announced at the end of the year.

An address on "Maintaining our Voluntary Hospital System" will be given by Rev. Monsignor Maurice F. Griffin of Cleveland. Dr. Arthur C. Bachmeyer of Chicago, Director of Study of the Commission on Hospital Care, will present "Pertinent Findings from the National Survey by the Commission on Hospital Care."

The program will conclude with a discussion of the nursing problem. Dr. Howard C. Naffziger of San Francisco, Professor of Surgery, University of California Medical School and Chairman of the Committee on Nursing, American Surgical Association, will present the viewpoint of the surgeon. Dr. Robin C. Buerki of Philadelphia, Director, University Hospitals and Dean of the Graduate School of Medicine, University of Pennsylvania, will present the viewpoint of the hospital administrator. Lucile Petry of Washington, Director of Nursing, United States Public Health Service, will present the viewpoint of the nurse.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening in the Music Hall of the Auditorium. The officers, regents, and distinguished guests will participate in the processional. Dr. W. Edward Gallie, President of the College, will preside. The address of welcome will be given by Dr. Thomas E. Jones, Chairman of the Cleveland Committee on Arrangements; distinguished guests will be introduced by Dr. Arthur W. Allen, Vice Chairman, Board of Regents; and Doctor Gallie will deliver the Presidential Address. An inaugural ceremony will be held for the incoming officers: President, Dr. Irvin Abell of Louisville; First Vice President, Dr. Leland S. McKittrick of Boston; Second Vice President, Dr. F. Philizy Calhoun of Atlanta.

The first Martin Memorial Lecture will be a feature of the Presidential Meeting this year. Dr. Edward D. Churchill of Boston has accepted the invitation to give this lecture, and his subject will be "The American Surgeon, A. U. S." The lec-

tuership was established upon motion of the Board of Regents at its midyear meeting on April 1, as a memorial to both Dr. Franklin H. Martin and Mrs. Martin. The founder of the College and of SURGERY, GYNECOLOGY AND OBSTETRICS, was joined by his wife in making the College the beneficiary at their deaths of the Journal, together with its physical plant operated by the Surgical Publishing Company of Chicago, of which they were the owners. Doctor Martin died in 1935 and Mrs. Martin in 1945.

The Martin Memorial Lecture, to be given annually during the Clinical Congress, and dealing with a scientific subject of the author's choosing, supplants the Annual Oration in Surgery.

CONVOCAION

The Convocation will be held on Friday evening in the Music Hall. It will open with a processional of officers, regents, governors, and initiates. The President, Dr. Irvin Abell, will preside and will confer the fellowships and the honorary fellowships. Dr. Arthur W. Allen, vice chairman of the Board of Regents, will present the candidates for fellowship.

Several hundred surgeons who have been received into fellowship *in absentia* during the war years in which no Convocation was held, will be added to the number of initiates for the current year who will be present to participate in the initiation ceremonies. The Convocation and in fact the meetings throughout the Congress will be occasions for reunion with many Fellows who have recently returned from service with the military forces.

FORUMS ON FUNDAMENTAL SURGICAL PROBLEMS

The Forums on Fundamental Surgical Problems will be conducted on Tuesday, Wednesday, Thursday, and Friday mornings from 9:00 to 12:30 o'clock, with two sessions held concurrently each morning, one in the Music Hall, the other in the Ballroom. Included in them will be brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties. No prepared discussions of the reports are planned, but questions and comments will be invited. Especially keen interest is expected in these sessions this year because of the accumulation of the results of 5 years of work since the last Clinical Congress. Dr. Owen H. Wangensteen of Minneapolis, chairman of the committee which is planning the program, is working toward representation of as many as possible of the various university departments of surgery

in this presentation of clinical and experimental research work.

The enlistment of the interest of young men who are doing original work, through the forums, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

GENERAL SURGERY

The evening symposia in general surgery on Tuesday, Wednesday, and Thursday, will be held at 8:00 o'clock in the Music Hall of the Public Auditorium. The subject for Tuesday night is "Care of the Patient Before and After Operation." The subject for Wednesday night is "Venous Thrombosis and Prevention of Pulmonary Embolism," to be followed by the annual Fracture Oration which will be delivered by Dr. Edwin W. Ryerson of Chicago, the subject being "Modern Methods in the Treatment of Fractures." The subject for Thursday night is "Antibiotic and Chemotherapeutic Agents in Surgery."

The subjects for the afternoon panel discussions in general surgery on Monday through Friday afternoons are as follows: "Rehabilitation of the Surgical Patient and Early Ambulation" on Monday at 1:30; "The Treatment of Cancer of the Large Bowel" on Monday at 3:30; "Thyroid Disease" on Tuesday at 1:30; "Recent Trends in the Management of Carcinoma of the Cervix" on Tuesday at 3:30; "Anesthesia" on Wednesday at 1:30; "Protein Metabolism in the Surgical Patient" on Wednesday at 3:30; "Spinal Cord Injuries" on Thursday at 3:30; "Surgery of the Stomach" on Friday at 1:30; and "Surgery of the Vascular System" on Friday at 3:30.

OPHTHALMOLOGY

The evening symposia in ophthalmology on Tuesday and Thursday will be held at 8:00 o'clock in South Hall B of the Cleveland Public Auditorium. "Orbital Reconstruction Including Prosthesis" will be the subject on Tuesday evening and several subjects will be discussed on Thursday.

Panel discussions on "Retinal Detachment," "Glaucoma," and "Keratoplasty," respectively, are scheduled for Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock.

OTORHINOLARYNGOLOGY

The evening symposia in otorhinolaryngology on Tuesday and Thursday will be held at 8:00 o'clock in South Hall C of the Cleveland Public Auditorium. "Treatment of Deafness" will be the subject on Tuesday evening and "Surgery of the Nasal Accessory Sinuses" on Thursday.

Panel discussions on "The Treatment of Ménière's Disease," "Osteomyelitis of the Skull," and "Rehabilitation of the War Deafened," respectively, are scheduled for Tuesday, Wednesday, and Thursday mornings at 11:00 o'clock.

PLASTIC SURGERY OF THE HEAD AND NECK

A special symposium on plastic surgery of the head and neck will be held on Wednesday evening at 8:00 o'clock in Club Room B. This symposium will be of interest to many general surgeons as well as to ophthalmologists and otorhinolaryngologists. The following subjects will be discussed: "Cancellous Bone Grafts to the Jaw"; "Repair of Nasal Defects with Free Composite Grafts of Skin and Cartilage from the Ear"; "Studies in the Anatomy and the Repair of Cleft Palate"; and "Preservation of Function Following Resections of Jaw Tumors."

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

"Advances from War Experience" is the general theme of the symposium on fractures and other traumas which has been arranged by Dr. Robert H. Kennedy of New York, chairman of the Committee on Fractures and Other Traumas of the American College of Surgeons. The aim is to give a rapid survey of worthwhile gains made during the war which may prove of lasting value in the field of trauma. This meeting will be held at 2:00 p.m. on Tuesday in the Ballroom of the Public Auditorium. From the outline shown on a succeeding page it will be seen that an impressive panel of 19 speakers will discuss different phases of the subject and that their presentations will be summarized by Vice Admiral Ross T. McIntire, Surgeon General of the United States Navy; Major General Norman T. Kirk, Surgeon General of the United States Army; and Major General Paul R. Hawley, Chief Medical Director of the United States Veterans Administration.

SYMPOSIUM ON CANCER

A symposium on cancer, sponsored by the Cancer Committee of the College, will be held at 2:00 o'clock on Wednesday afternoon in the Ballroom of the Cleveland Public Auditorium. Dr. Frank E. Adair, chairman of the committee, will preside. The subjects to be discussed are the following: "Surgical Treatment of Cancer of the Pancreas," "Resections of Abdominal Cancer Infiltrating the Abdominal Wall," "Hormone Therapy in Cancer of the Prostate," "Estrogen Therapy in Cancer of the Breast," "Testosterone in Cancer of the Breast"; and "Observations on the Genetic Nature of Gastric Cancer in Mice."

GRADUATE TRAINING IN SURGERY

A panel discussion on graduate training in surgery and the surgical specialties will be held Thursday afternoon at 3:00 o'clock in the Ballroom. Discussion will be from the standpoints of the American College of Surgeons, the basic medical sciences, the Veterans Administration, the university-connected hospital, and the hospital which is not connected with a university.

HOSPITAL STANDARDIZATION CONFERENCE

The twenty-fifth annual Hospital Standardization Conference will open on Monday morning at 9:30 o'clock with the joint session for surgeons and hospital representatives in the Music Hall of the Public Auditorium. The program for this General Assembly has been outlined previously.

The Monday afternoon session will be held in the Ballroom of the Public Auditorium and will consist of a panel discussion on current problems and the immediate outlook in nursing service, conducted by John H. Hayes of New York, President of the American Hospital Association. Among the subjects included will be the following: "Nursing Standards as Affected by Personnel Policies," "Postwar Student Nurse Recruitment Problems," "The Training of a Secondary Group for Nursing Service," and "Nursing Education and Nursing Service."

The Tuesday morning session will be held in Club Room B of the Public Auditorium and will consist of a panel discussion on the securing of complete and scientific medical records. The chairman, Everett W. Jones of Chicago, Vice President of the Modern Hospital Publishing Company, will discuss, "Status of Medical Records in Hospitals as I have Observed Them," following which the program of the American Association of Medical Record Librarians to improve medical record science will be presented. The importance of complete and scientific medical records will then be discussed by different speakers from the standpoints of better care of the patient, training of interns and residents, and the advancement of medical science. The meeting will conclude with a round table conference.

The Tuesday afternoon session in Club Room B will be devoted to a panel discussion on "Extending General Hospital Service to all Types of Patients," with Dr. Herman Smith of Chicago, hospital consultant, presiding. Trends in the care of psychiatric, tuberculous, chronically ill, and orthopedic patients will be discussed by authoritative speakers. The concluding talk will be on "Integration of Health Services in the Community" by Graham L. Davis of Battle Creek.

PRELIMINARY PROGRAM—1946 CLINICAL CONGRESS

825

President-Elect of the American Hospital Association.

Tuesday evening in the Little Theatre of the Cleveland Public Auditorium there will be a joint session for hospital trustees, medical staff officers, and administrators, with Dr. Fred G. Carter of Cleveland presiding.

Wednesday morning at 7:45 a breakfast conference on hospital public relations will be held at the Hotel Statler.

The responsibility of the administrative staff in handling emergencies coming to the hospital and discussion on Wednesday morning at 9:30 in Club Room B of the Public Auditorium, which will be conducted by Dr. Frank R. Bradley of St. Louis, Director of Barnes Hospital and President of the American College of Hospital Administrators.

The Wednesday afternoon meeting in Club Room B will consist of a panel discussion on the training of hospital personnel. This will be conducted by Dr. Claude C. Munger of New York, Administrator of St. Luke's Hospital, and Director of the school of hospital administration at Columbia University. Subjects for discussion include the following: "University Training for Hospital Administration"; "Establishing Administrative Internships or Residencies on a High Educational Level"; "Training Supervisory Personnel," and "Training Personnel Managers."

The meeting on Wednesday evening in the Little Theatre of the Public Auditorium will consist of a round table conference on current hospital problems. This will be conducted by Dr. Harvey Agnew of Toronto, Secretary of the Canadian Hospital Council.

The Thursday morning program will begin with a breakfast conference at 7:45 at the Statler Hotel on the subject, "The Point Rating System as Applied to Hospitals," with Dr. Malcolm T. MacEachern presiding. At 9:30 in Club Room B of the Public Auditorium there will be a panel discussion on management techniques and personnel relations conducted by James A. Hamilton of Minneapolis.

The Thursday afternoon program will consist of two sessions. The first, to be held from 2:00 to 5:00 o'clock in Club Room B, will be a panel discussion on problems of the small hospital conducted by Jane Davis of Niles, Michigan, superintendent of Pawating Hospital. The second will be held in the Ballroom from 3:00 to 5:30 o'clock and will be a joint conference of hospital representatives and surgeons on graduate training in surgery and the surgical specialties, with Dr. Robin C. Buerki of Philadelphia.

ASSEMBLY OF INITIATES

The Assembly of Initiates will be held on Friday afternoon in the Ballroom of the Cleveland Public Auditorium. Dr. Irvin Abell, president, will preside. "The Program of the American College of Surgeons" will be discussed by Dr. Malcolm T. MacEachern, Dr. Bowman C. Crowell, and Major General Charles R. Reynolds (Ret.). Dr. Arthur W. Allen, vice chairman, Board of Regents, will speak on "Fellowship in the American College of Surgeons." The program will close with the recital of the fellowship pledge by the initiates.

NATIONAL AND REGIONAL FRACTURE COMMITTEES

The meeting of the National and Regional Fracture Committees, with Dr. Robert H. Kennedy, of New York, chairman of the National Committee, presiding, will be held on Wednesday afternoon in Club Room A of the Cleveland Public Auditorium, when this assembly of surgeons will discuss the activities of the respective groups. Working in co-operation with the American Red Cross, these committees have exerted great influence in improving methods and facilities for the transportation of the injured. They have also made a concerted effort to improve the treatment of fractures in the hospitals of many communities. Personal problems will be discussed at the meeting of these committees.

ANNUAL MEETING OF COMMITTEES

The annual meetings of the State and Provincial Judiciary, Credentials, and Executive Committees will be held on Wednesday morning in the Ballroom of the Hotel Statler. These committees have an important function to perform in the College. The Credentials Committees and the Committees on Applicants constitute one of the largest and most carefully deliberate accrediting bodies which exist in the medical profession. Through this organization the standards of fellowship are maintained and each Fellow of the College has a definite responsibility in this work. All members of these committees are urged to attend this important meeting.

ANNUAL MEETING OF FELLOWS

The annual meeting of the Governors and Fellows will be held on Thursday afternoon at 1:45. There will be election of officers and governors. The annual meeting affords the Fellows of the College an opportunity to hear reports of officials on the work of the organization, and to learn how it has not only raised the professional and ethical

standards of surgery, but has also promoted good hospitalization and general improvement in the practice of medicine in the United States and Canada. Each Fellow has a personal part in this work and may extend the influence of the College materially in his local community. Hospital Standardization alone offers him unlimited opportunity to provide better medical care for his patients in the hospital in which he works, through continuous progress in applying the principles of the Minimum Standard which insure the best care of the patient.

Every Fellow will want to attend this important meeting, at which reports will be presented on finances; Hospital Standardization; Graduate Training in Surgery; Medical Motion Pictures, Publications; Public Relations; Library and Literary Research; the work of the state and provincial credentials committees, committees on applicants, and the Committee on History Reviews; Sectional Meetings, 1946; and the Department of Clinical Research, including cancer clinics, Medical Service in Industry, Cancer Committee, and the Committee on Fractures and other Traumas. Dr. Abell will report on administration of the College, staff changes, and retirements, and Dr. Arthur W. Allen, Vice-Chairman of the Board of Regents will discuss "Fellowship Obligations and Opportunities."

MEDICAL MOTION PICTURES

The latest available films showing surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily. Films on general surgery will be shown in the Little Theatre and films on ophthalmology and otorhinolaryngology in South Hall A of the Cleveland Public Auditorium. These are a much appreciated feature of the Clinical Congress. Despite the decrease in production of such films during the war period, a surprising number of new pictures on varied subjects are being received by the American College of Surgeons for review. Both sound and silent, colored films will be shown, all of which have been approved by the Committee on Medical Motion Pictures.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaus, will be held in the Arena of the Cleveland Public Auditorium. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, pharmaceuticals, and publishers of medical books will be represented in the exhibi-

tion. The technical exhibits will demonstrate many of the newer features learned from our experience in the war.

REGISTRATION

Fellows of the College whose dues are paid to December 31, 1945, initiates of the classes of 1942 through 1946, and Fellows in military service will not be required to pay a registration fee for the Clinical Congress. For endorsed junior residents the fee is \$5.00. Surgeons, not Fellows, who attend as invited guests of the College will pay a registration fee of \$10.00.

Although the hospitals of Cleveland afford accommodations for a considerable number of visiting surgeons, attendance at the Congress will be limited to the number that can be comfortably accommodated at the various meetings, as well as by the local hotels. It is anticipated, therefore, that surgeons who are planning to attend the Congress will have registered for the Congress and will also have a confirmed hotel reservation in advance.

HOTEL SITUATION IN CLEVELAND

As a result of the great number of early registrants, practically all of the available hotel space in Cleveland has already been reserved. A number of the Fellows desiring to attend this Congress have been unable to the present time to secure hotel accommodations, and their names have now been placed on a waiting list with the Cleveland Convention Bureau.

The Officers and Regents of the College wish to do all they can to aid in obtaining accommodations for all who want to attend. Arrangements have been made with the Cleveland Convention Bureau to care for a considerable number in private homes in the Cleveland area as well as in the Mayflower and Portage hotels in nearby Akron, which has frequent train and bus service to Cleveland. The average running time of these services from Akron to Cleveland is about one hour, and if the situation warrants, an effort will be made to provide chartered bus service.

Those who desire to attend this Congress and as yet have been unable to secure a room reservation in Cleveland should write immediately to Mr. Edward C. Brennan, Executive Director, Cleveland Convention Bureau, 511 Tower Building, Cleveland, Ohio. The accommodations desired, the dates of arrival and departure should be given. Information should also be furnished as to whether a reservation in a private home in Cleveland or in an Akron hotel would be acceptable. A reservation in a Cleveland hotel is not available.

CLINICAL CONGRESS PROGRAM IN BRIEF

UNLESS OTHERWISE DESIGNATED, THE MEETING ROOMS LISTED ARE IN THE CLEVELAND PUBLIC AUDITORIUM

Monday

- 9:30 General Assembly for Surgeons and Hospital Representatives, Music Hall
- 1:30 Panel Discussion, Music Hall
- 2:00 Hospital Conference, Ballroom
- 2:00 Surgical Film Exhibition (General), Little Theatre
- 3:30-5:00 Panel Discussion, Music Hall
- 8:15 Presidential Meeting, Music Hall

Tuesday

- 8:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 9:00 Forum on Fundamental Surgical Problems, Section A, Music Hall; Section B, Ballroom
- 9:30 Hospital Conference, Club Room B
- 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), South Hall A
- 10:00 Surgical Film Exhibition (General), Little Theatre
- 11:00 Panel Discussions
 - Ophthalmology, South Hall B
 - Otorhinolaryngology, South Hall C
- 1:30 Panel Discussion, Music Hall
- 2:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 2:00 Hospital Conference, Club Room B
- 2:00 Symposium on Fractures and Other Traumas, Ballroom
- 2:00 Surgical Film Exhibition (General), Little Theatre
- 3:30 Panel Discussion, Music Hall
- 7:00 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), South Hall A
- 7:30 Hospital Conference, Little Theatre
- 8:00 Symposium, General Surgery, Music Hall
- 8:00 Symposium, Ophthalmology, South Hall B
- 8:00 Symposium, Otorhinolaryngology, South Hall C

Wednesday

- 7:45 Hospital Breakfast Conference, Lattice Room, Hotel Statler
- 8:00 Meeting of Cancer Committee, Tavern Room, Hotel Statler
- 8:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 9:00 Forum on Fundamental Surgical Problems, Section A, Music Hall; Section B, Ballroom
- 9:30 Hospital Conference, Club Room B
- 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), South Hall A
- 10:00 Surgical Film Exhibition (General), Little Theatre

State and Provincial Committees:

- 9:30 Executive Committees, Ballroom, Hotel Statler
- 10:15 Credentials Committees and Committees on Applicants, Ballroom, Hotel Statler
- 11:00 Judiciary Committees, Ballroom, Hotel Statler
- 11:00 Panel Discussions
 - Ophthalmology, South Hall B
 - Otorhinolaryngology, South Hall C
- 12:00 Meeting of Board of Governors, Lattice Room, Hotel Statler
- 1:30-3:00 Panel Discussion, Music Hall
- 2:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 2:00 Symposium on Cancer, Ballroom
- 2:00 Surgical Film Exhibition (General), Little Theatre

- 2:30 Hospital Conference, Club Room B
- 3:30-5:00 Panel Discussion, Music Hall
- 3:30 National and Regional Fracture Committees, Club Room A
- 7:00 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), South Hall A
- 7:30 Hospital Conference, Little Theatre
- 8:00 Symposium, General Surgery, Music Hall
- 8:00 Symposium, Plastic Surgery of the Head and Neck, Club Room B

Thursday

- 7:45 Hospital Breakfast Conference, Lattice Room, Hotel Statler
- 8:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 9:00 Forum on Fundamental Surgical Problems, Section A, Music Hall; Section B, Ballroom
- 9:30 Hospital Conference, Club Room B
- 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), South Hall A
- 10:00 Surgical Film Exhibition (General), Little Theatre
- 11:00 Panel Discussions
 - Ophthalmology, South Hall B
 - Otorhinolaryngology, South Hall C
- 1:30 Adjourned Meeting, Governors, Music Hall
- 1:45 Annual Meeting, Fellows, Music Hall
- 2:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 2:00 Hospital Conference, Club Room B
- 3:00 Panel Discussion—Graduate Training in Surgery, Ballroom
- 3:30 Panel Discussion, Music Hall
- 3:30 Surgical Film Exhibition (General), Little Theatre
- 4:00 Committee on the Library, Club Room A
- 7:00 Surgical Film Exhibition (Ophthalmology, and Otorhinolaryngology), South Hall A
- 8:00 Symposium, General Surgery, Music Hall
- 8:00 Symposium, Ophthalmology, South Hall B
- 8:00 Symposium, Otorhinolaryngology, South Hall C

Friday

- 8:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 9:00 Forum on Fundamental Surgical Problems, Section A, Music Hall; Section B, Ballroom
- 9:30 Surgical Film Exhibition (Ophthalmology and Otorhinolaryngology), South Hall A
- 10:00 Surgical Film Exhibition (General), Little Theatre
- 1:00 Assembly of Initiates, Ballroom
- 1:30 Panel Discussion, Surgery of the Stomach, Music Hall
- 2:00 Clinics, Demonstrations and Group Conferences, Selected local hospitals
- 2:00 Panel Discussions
 - Obstetrics, South Hall A
 - Plastic Surgery, Club Room C
 - Neurological Surgery, Club Room A
 - Thoracic Surgery, South Hall B
 - Urology, South Hall C
 - Orthopedic Surgery, Club Room B
- 2:00 Surgical Film Exhibition (General), Little Theatre
- 3:30 Panel Discussion, Surgery of the Vascular System, Music Hall
- 8:15 Convocation, Music Hall

GENERAL ASSEMBLY

Monday, 9:30 a.m.—Music Hall, Public Auditorium

Opening Session of Clinical Congress—General Assembly

W. EDWARD GALLIE, M.D., Toronto; President, American College of Surgeons, Presiding

Preliminary Statement. W. EDWARD GALLIE, M.D., Toronto.

Presentation of Report of Field Activities of the American College of Surgeons for 1946, and Summary of 28 Years of Hospital Standardization.

IRVIN ABELL, M.D., Louisville; Chairman, Board of Regents, American College of Surgeons.

Maintaining our Voluntary Hospital System. Right Reverend Monsignor MAURICE F. GRIFFIN, Cleveland

Pertinent Findings from the National Survey by the Commission on Hospital Care.

ARTHUR C. BACHMEYER, M.D., Chicago; Director of Study, Commission on Hospital Care; Director, University of Chicago Clinics.

The Nursing Problem:

The Viewpoint of the Surgeon.

HOWARD C. NAFFZIGER, M.D., San Francisco; Professor of Surgery, University of California Medical School; Chairman, Committee on Nursing, American Surgical Association.

The Viewpoint of the Administrator.

ROBIN C. BUERKI, M.D., Philadelphia; Director, University Hospitals and Dean of the Graduate School of Medicine, University of Pennsylvania.

The Viewpoint of the Nurse.

LUCILE PETRY, R.N., Washington; Chief of the Division of Nursing, United States Public Health Service.

PRESIDENTIAL MEETING

Monday, 8:15 p.m.—Music Hall, Public Auditorium

W. EDWARD GALLIE, M.D., Toronto; President, American College of Surgeons, Presiding.

Processional—Officers, Regents and Distinguished Guests.

Invocation.

Rev. BEVERLEY D. TUCKER, D.D., LL.D., Cleveland; Bishop of the Diocese of Ohio.

Address of Welcome.

THOMAS E. JONES, M.D., Cleveland; Chairman, Committee on Arrangements.

Introduction of Distinguished Guests.

ARTHUR W. ALLEN, M.D., Boston; Vice Chairman, Board of Regents.

Address of the Retiring President. Ideals in Surgery.

W. EDWARD GALLIE, M.D., Toronto.

Inauguration of Officers Presented by ALBERT G. FURSTENBERG, M.D., Ann Arbor; Second Vice President.

President: IRVIN ABELL, M.D., Louisville.

First Vice President: LELAND S. MCKITTRICK, M.D., Boston.

Second Vice President: F. PHINIZY CALHOUN, M.D., Atlanta.

The Martin Memorial Lecture. The American Surgeon, A.U.S.

EDWARD D. CHURCHILL, M.D., Boston. John Homans Professor of Surgery, Harvard University.

Recessional.

CONVOCATION

Friday, 8:15 p.m.—Music Hall, Public Auditorium

IRVIN ABELL, M.D., Louisville; President, Presiding.

Processional. Initiates, Officers, Regents and Distinguished Guests.

Invocation.

Right Reverend Monsignor MAURICE F. GRIFFIN, Cleveland.

Conferring of Fellowships by the President.

IRVIN ABELL, M.D., Louisville.

Fellowship Pledge. Recital by the Initiates.

Conferring of Honorary Fellowships. The President.

Fellowship Address. The Education of a Physician.

REUBEN G. GUSTAVSON, Ph.D., Omaha; Chancellor, University of Nebraska.

Recessional.

Reception by the Officers and Regents for the Initiates and Fellows.

OTORHINOLARYNGOLOGY

Symposia

Tuesday, 8:00 p.m.—South Hall C, Public Auditorium

CARL H. McCASKEY, M.D., Indianapolis; Member, Advisory Council for Otorhinolaryngology, American College of Surgeons, Presiding.

Treatment of Deafness

The Management of the Chronic Suppurating Ear. JAMES H. MAXWELL, M.D., Ann Arbor.

The Fenestration Operation. GEORGE E. SHAMBAUGH, JR., M.D., Chicago.

The Use of Radium for Conductive Deafness. JOHN E. BORDLEY, M.D., Baltimore.

Thursday, 8:00 p.m.—South Hall C, Public Auditorium

DAVID H. BALLON, M.D., Montreal; Chairman of the Department of Otolaryngology, McGill University Faculty of Medicine, Presiding.

Surgery of the Nasal Accessory Sinuses

Indications for Surgery in the Light of the Use of Antibiotics. HARRY P. SCHENK, M.D., Philadelphia.

Intranasal Surgery. JOHN J. SHEA, M.D., Memphis.

External Operation. FRANCIS L. WELIE, M.D., Boston.

PLASTIC SURGERY OF THE HEAD AND NECK

Wednesday, 8:00 p.m.—Club Room B, Public Auditorium

Symposium

GORDON B. NEW, M.D., Rochester, Minnesota; Member Advisory Council for Otorhinolaryngology, American College of Surgeons, Presiding.

Cancellous Bone Grafts to the Jaw. TRUMAN G. BLOCKER, M.D., Galveston.

Repair of Nasal Defects with Free Composite Grafts of Skin and Cartilage from the Ear. JAMES B. BROWN, M.D., St. Louis, and Lt. Col. BRADFORD CANNON, M.C., Valley Forge.

Studies in the Anatomy and the Repair of Cleft Palate. GEORGE M. DORRANCE, M.D., Philadelphia.

Preservation of Function Following Resections of Jaw Tumors. LOUIS T. BYARS, M.D., St. Louis, and

FRANK McDOWELL, M.D., St. Louis.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

ADVANCES FROM WAR EXPERIENCE

Tuesday, 2:00 p.m.—Ballroom, Public Auditorium

ROBERT H. KENNEDY, M.D., New York; Chairman, Committee on Fractures and Other Traumas, Presiding

Shock and Hemorrhage. CHARLES S. RIFE, M.D., Milwaukee.

Burns. Captain H. L. PUGH, M.C., U. S. Navy, Bethesda.

Injuries to the Chest. EARLE B. KAY, M.D., Cleveland.

Injuries to the Genitourinary Tract: Emphasis on Urethral Injuries. GEORGE C. PRATHER, M.D., Boston.

Injuries to the Rectum. EDMUND J. CROCE, M.D., Worcester.

Herniated Nucleus Pulposus. WINCHELL McK. CRAIG, M.D., Rochester.

Spinal Cord Injuries. DAVID H. POER, M.D., Atlanta.

Peripheral Nerves. BENJAMIN B. WHITCOMB, M.D., Hartford.

Hand Surgery. WILLIAM H. FRACKELTON, M.D., Milwaukee.

Fractures of the Carpal Scaphoids. MATHER CLEVELAND, M.D., New York.

Transportation of Fractures. WILLIAM J. STEWART, M.D., Columbia.

Management of Compound Fractures in Their Early Phases. OSCAR P. HAMPTON, JR., M.D., St. Louis

Osteomyelitis following Compound Fractures. GROVER C. PENBERTHY, M.D., Detroit.

Replacement of Skin Defects. JAMES B. BROWN, M.D., St. Louis.

Paravertebral Block and Sympathectomy. HARRIS B. SHUMACKER, JR., M.D., New Haven.

Bone Grafts. GEORGE K. CARPENTER, M.D., Nashville.

Amputations. RUFUS H. ALDREDGE, M.D., New Orleans.

Training of Amputees. HENRY H. KESSLER, M.D., Newark.
 Rehabilitation. LT. COL. A. WILLIAM REGGIO, Washington, D.C.
 Brief Summary:

MAJOR GENERAL PAUL R. HAWLEY (Ret.), Washington; Chief Medical Director, U.S. Veterans Administration.

VICE ADMIRAL ROSS T. MCINTIRE, Washington; The Surgeon General of the Navy.

MAJOR GENERAL NORMAN T. KIRK, Washington; The Surgeon General of the Army.

SYMPOSIUM ON CANCER

Wednesday, 2:00 p.m.—Ballroom, Public Auditorium

FRANK E. ADAIR, M.D., New York; Chairman, Cancer Committee, American College of Surgeons, Presiding
 Surgical Treatment of Cancer of the Pancreas. RICHARD B. CATTELL, M.D., Boston.

Resections of Abdominal Cancer Infiltrating the Abdominal Wall. ALEXANDER BRUNSWIG, M.D., Chicago.

Hormone Therapy in Cancer of the Prostate. WILLIAM W. SCOTT, M.D., Baltimore.

Estrogen Therapy in Cancer of the Breast. IRA T. NATHANSON, M.D., Boston.

Testosterone in Cancer of the Breast. FRANK E. ADAIR, M.D., New York.

Observations on the Genetic Nature of Gastric Cancer in Mice. LEONELL C. STRONG, Ph.D., New Haven.

GRADUATE TRAINING IN SURGERY AND THE SURGICAL SPECIALTIES

PANEL DISCUSSION

Thursday, 3:00 p.m.—Ballroom, Public Auditorium

Graduate Training in Surgery and the Surgical Specialties

Moderator: ROBIN C. BUECKI, M.D., Philadelphia

The American College of Surgeons

MAJOR GENERAL CHARLES R. REYNOLDS (Ret.), Chicago

The Basic Medical Sciences

GEORGE H. MILLER, M.D., Chicago

The Veterans Administration

PAUL B. MAGNUSON, M.D., Washington

The University-Connected Hospital

JOHN R. PAINE, M.D., Minneapolis

The Hospital Not University-Connected

GEORGE J. CURRY, M.D., Flint

PANEL DISCUSSIONS

GENERAL SURGERY

Monday, 1:30-3:00 p.m.—Music Hall, Public Auditorium

Rehabilitation of the Surgical Patient and Early Ambulation

Moderator: HOWARD RUSK, M.D., New York

Collaborators: I. S. RAYDIN, M.D., Philadelphia

HENRY H. KESSLER, M.D., Newark

JOHN H. POWERS, M.D., Cooperstown

Monday, 3:30-5:00 p.m.—Music Hall, Public Auditorium

The Treatment of Cancer of the Large Bowel

Moderator: FREDERICK A. COLLIER, M.D., Ann Arbor

Collaborators: THOMAS E. JONES, M.D., Cleveland

CLAUDE F. DIXON, M.D., Rochester, Minnesota

FRED W. RANKIN, M.D., Lexington

Tuesday, 1:30-3:00 p.m.—Music Hall, Public Auditorium

Thiouracil in Thyroid Disease

Moderator: FRANK LAHEY, M.D., Boston

Collaborators: GEORGE M. CURTIS, M.D., Columbus

WARREN H. COLE, M.D., Chicago

EIMER C. HARTTIS, M.D., Boston

Tuesday, 3:30-5:00 p.m.—Music Hall, Public Auditorium

Recent Trends in the Management of Carcinoma of the Cervix

Moderator: JOE V. MEIGS, M.D., Boston

Collaborators: RICHARD W. TELINDE, M.D., Baltimore

CHARLES A. BEHNEY, M.D., Philadelphia

RICHARD DRESSER, M.D., Boston

Wednesday, 1:30-3:00 p.m.—Music Hall, Public Auditorium

Anesthesia

Moderator: HENRY K. BEECHER, M.D., Boston

Collaborators: URBAN H. EVERSOLE, M.D., Boston

LOYD H. MOUSEL, M.D., Rochester, Minnesota

STUART C. CULLEN, M.D., Iowa City

Wednesday, 3:30-5:00 p.m.—Music Hall, Public Auditorium

Protein Metabolism in the Surgical Patient

Moderator: ROBERT ELMAN, M.D., St. Louis

Collaborators: CHARLES C. LUND, M.D., Boston

PAUL R. CANNON, M.D., Chicago

JOHN H. MULHOLLAND, M.D., New York

Thursday, 3:30-5:00 p.m.—Music Hall, Public Auditorium

Spinal Cord Injuries

Moderator: HOWARD C. NAFFZIGER, M.D., San Francisco

Collaborators: FRANCIS C. GRANT, M.D., Philadelphia

ROBERT H. KENNEDY, M.D., New York

LEWIS J. POLLOCK, M.D., Chicago

Friday, 1:30-3:00 p.m.—Music Hall, Public Auditorium

Surgery of the Stomach

Moderator: ROSCOE R. GRAHAM, M.D., Toronto

Collaborators: G. GAVIN MILLER, M.D., Montreal

LESTER R. DRAGSTEDT, M.D., Chicago

HOWARD K. GRAY, M.D., Rochester, Minnesota

Friday, 3:30-5:00 p.m.—Music Hall, Public Auditorium

Surgery of the Vascular System

Moderator: DANIEL C. ELKIN, M.D., Atlanta

Collaborators: ALFRED BLALOCK, M.D., Baltimore

ARTHUR H. BLAKEMORE, M.D., New York

MICHAEL E. DEBAKEY, M.D., New Orleans

SURGICAL SPECIALTIES

Urology

Friday, 2:00-5:00 p.m.—South Hall C, Public Auditorium

Management of Spinal Cord Bladders

Moderator: HERMAN L. KRETSCHMER, M.D., Chicago

Collaborators: MICHAEL K. O'HEEREN, M.D., Houston. From the Standpoint of the Urologist

PHILIP LEWIN, M.D., Chicago. From the Standpoint of the Orthopedist

FRANK H. MAYFIELD, M.D., Cincinnati. From the Standpoint of the Neurologist

FRANK H. KRUSEN, M.D., Rochester, Minnesota. From the Standpoint of the Physical Therapist

Cancer of the Bladder—An Appraisal of Present Day Methods of Treatment

Moderator: HERMAN L. KRETSCHMER, M.D., Chicago

Collaborators: GERSHOM J. THOMPSON, M.D., Rochester, Minnesota. Conservative Transurethral Treatment of Bladder Tumors

F. H. SQUIRE, M.D., Chicago. Radiation Treatment

CHARLES C. HIGGINS, M.D., Cleveland. Cystectomy with Transplantation of the Ureters to the Bowel or Skin

Neurological Surgery

Friday, 2:00—5:00 p.m.—Club Room A, Public Auditorium

Ruptured Intervertebral Discs

Moderator: FRANCIS C. GRANT, M.D., Philadelphia

Collaborators: WILLIAM P. VANWAGENEN, M.D., Rochester, New York

RUDOLPH JAEGER, M.D., Philadelphia

JAMES L. POPPEN, M.D., Boston

Orthopedic Surgery

Friday, 2:00—5:00 p.m.—Club Room B, Public Auditorium

Intra-Articular Fractures of the Elbow in Childhood and Adult Life

Moderator: CARL E. BAUGLEY, M.D., Ann Arbor

Collaborators: PHILIP D. WILSON, M.D., New York

HAROLD B. BOYD, M.D., Memphis

CLAY R. MURRAY, M.D., New York

The Treatment of Club Foot and Its Complications

Moderator: CARL E. BAUGLEY, M.D., Ann Arbor

Collaborators: JOSEPH H. KITE, M.D., Atlanta

FRANK R. OBER, M.D., Boston

FRANK E. CURTIS, M.D., Detroit

Plastic Surgery

Friday, 2:00—5:00 p.m.—Club Room C, Public Auditorium

Early Skin Grafting of Burns

Moderator: ROBERT H. IVY, M.D., Philadelphia

Collaborators: JEROME P. WEBSTER, M.D., New York

HARVEY S. ALLEN, M.D., Chicago

Use of Flaps and Grafts in Reconstructive Surgery of the Extremities

Moderator: ROBERT H. IVY, M.D., Philadelphia

Collaborators: Major CARL E. LISCHER, M.C., Valley Forge

Major WILLIAM B. DAVIS, M.C., Valley Forge

Obstetrics

Friday, 2:00—5:00 p.m.—South Hall A, Public Auditorium

Common Problems of the Obstetrician and Pediatrician in Neonatal Morbidity

Moderator: THADDEUS L. MONTGOMERY, M.D., Philadelphia

Collaborators: FREDERICK H. FALLS, M.D., Chicago

WALDO E. NELSON, M.D., Philadelphia

Uterine Inertia

Moderator: THADDEUS L. MONTGOMERY, M.D., Philadelphia

Collaborators: DOUGLAS P. MURPHY, M.D., Philadelphia

FREDERICK H. FALLS, M.D., Chicago

*Thoracic Surgery**Friday, 2:00-5:00 p.m.—South Hall B, Public Auditorium**Treatment of Carcinoma of the Esophagus**Lung Resection in Pulmonary Tuberculosis*

Moderator: RICHARD H. SWEET, M.D., Boston

Collaborators: JOHN M. GARLOCK, M.D., New York

WILLIAM E. ADAMS, M.D., Chicago

HERBERT C. MAIER, M.D., New York

OPHTHALMOLOGY

*Tuesday, 11:00 a.m.—South Hall B, Public Auditorium**Retinal Detachment*

Moderator: PAUL A. CHANDLER, M.D., Boston

Collaborators: DONALD W. BOGART, M.D., New York

PETER C. KRONFELD, M.D., Chicago

A. D. RUEDEMANN, M.D., Cleveland

*Wednesday, 11:00 a.m.—South Hall B, Public Auditorium**Glaucoma*

Moderator: SAMUEL J. MEYER, M.D., Chicago

Collaborators: H. SAUL SUGAR, M.D., Chicago

THOMAS D. ALLEN, M.D., Chicago

*Thursday, 11:00 a.m.—South Hall B, Public Auditorium**Keratoplasty*

Moderator: R. TOWNLEY PATON, M.D., New York

Collaborators: DERRICK T. VAIL, JR., M.D., Chicago

HERBERT M. KATZIN, M.D., New York

J. WESLEY MCKINNEY, M.D., Memphis

OTORHINOLARYNGOLOGY

*Tuesday, 11:00 a.m.—South Hall C, Public Auditorium**The Treatment of Ménière's Disease*

Moderator: ALBERT C. FURSTENBERG, M.D., Ann Arbor

Collaborators: KENNETH M. DAY, M.D., Pittsburgh

JOHN R. LINDSAY, M.D., Chicago

THEODORE E. WALSH, M.D., St. Louis

*Wednesday, 11:00 a.m.—South Hall C, Public Auditorium**Osteomyelitis of the Skull*

Moderator: JOSEPH E. J. KING, M.D., New York

Collaborators: ALBERT C. FURSTENBERG, M.D., Ann Arbor

EDGAR F. FINCHER, M.D., Atlanta

*Thursday, 11:00 a.m.—South Hall C, Public Auditorium**Rehabilitation of the War Deafened*

Moderator: NORTON CANFIELD, M.D., New Haven

Collaborators: FRANCIS L. LEDERER, M.D., Chicago

RAYMOND CARHART, Ph.D., Evanston

HERBERT KOEPP-BAKER, Ph.D., Chicago

CHARLES E. KINNEY, M.D., Cleveland

PRELIMINARY PROGRAM—1946 CLINICAL CONGRESS
FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

Tuesday, 9:00 a. m.—Music Hall, Public Auditorium

WARREN H. COLE, M.D., Chicago, Presiding.

Intestines and Thyroid

Effect of Early Postoperative Rising on the Recurrence Rate of Hernia. JAMES B. BLODGETT, M.D., and EDWARD J. BEATTIE, M.D., Boston. Department of Surgery, Harvard Medical School—Peter Bent Brigham Hospital.

The Relation of Transverse Abdominal Incisions and Early Ambulation to the Reduction of Postoperative Complications. KENNETH F. MACLEAN, M.D., and JAMES THOMPSON, M.D., Ann Arbor. Department of Surgery, University of Michigan Medical School.

A New Method for the Roentgenologic Study of the Rectum. GEORGE LEVENE, M.D., Boston. Surgical Service, Massachusetts Memorial Hospitals, and Department of Surgery, Boston University School of Medicine.

Statistical Analysis—Carcinoma of the Colon. WILLIAM J. VYNALEK, M.D., Berwyn, Illinois. Department of Surgery, Veterans Administration Hospital, Hines; and Department of Surgery, Loyola University School of Medicine.

Reconstruction of the Colon and Rectum Following Battle Wounds. DAVID HENRY POER, M.D., Atlanta. Emory University School of Medicine.

Experiences with the Dragstedt Ileostomy. GEORGE BENTON SANDERS, M.D., Louisville. Surgical Service, Vaughan General Hospital, Hines, Illinois; and Department of Surgery, University of Louisville School of Medicine.

The Role of Infection in Experimental Closed Loop Small Bowel Obstruction. EARLE B. MAHONEY, M.D., JOHN A. SCHILLING, M.D., HARRY D. KINGSLEY, M.D., and WALTER A. GUNKLER, M.D., Rochester, New York. Strong Memorial Hospital.

The Effect of Penicillin in Experimental Intestinal Obstruction. ALEXANDER BLAIN, III, M.D., Ann Arbor. Department of Surgery, University Hospital.

Laboratory and Clinical Experiences with the Use of Streptomycin in the Prophylaxis and Treatment of Infections of Intestinal Origin. HENRY L. SILVANI, M.D., SANFORD ROTHENBERG, M.D., HELEN WARMER, JOYCE AMLUXEN, and H. J. McCORKLE, M.D., San Francisco. Department of Experimental Surgery, University of California Medical School.

Thiouracil and Iodine: The Preoperative Management of the Thyrotoxic Patient. BENJAMIN GOLDMAN, M.D., JAMES WEAVER, M.D., and E. M. RALSTON, M.D., Erie, Pennsylvania. Hamot Hospital.

The Necessity for and Methods of Remedying the Disturbances of Calcium and Phosphorus Metabolism in Patients with Toxic Goiter. I. DARIN PUFFEL, M.D., Columbus, Ohio. Department of Research Surgery, Ohio State University College of Medicine.

Tuesday, 9:00 a.m.—Ballroom, Public Auditorium

FREDERICK A. COLLIER, M.D., Ann Arbor, Presiding.

Vascular Surgery

Wounds of Common Carotid Arteries. KNOWLES B. LAWRENCE, M.D., Brookline. Surgical Service, Massachusetts Memorial Hospitals; and Department of Surgery, Boston University School of Medicine.

Ligation of the Inferior Vena Cava in Thrombosis of the Deep Veins of the Lower Extremities. J. ROSS VEAL, M.D., Washington, D.C. Georgetown University School of Medicine.

Ligation of the Inferior Vena Cava. WILLIAM R. MOSES, M.D., Washington, D.C. Department of Surgery, George Washington University School of Medicine; and Gallinger Municipal Hospital.

- Permanent Intubation Anastomosis of the Thoracic Aorta. CHARLES A. HUFNAGER, M.D., Boston. Department of Surgery, Harvard Medical School—Peter Bent Brigham Hospital.
- The Indications for Porta-caval Anastomosis. ARTHUR H. BLAKEMORE, M.D., New York. Department of Surgery, Columbia University College of Physicians and Surgeons.
- Abdominal Arteriography. Report of Complete Aortic Block. FREDERICK B. WAGNER, JR., M.D., and ALISON H. PRICE, M.D., Philadelphia. Samuel D. Gross Surgical Division and Medical Department, Jefferson Medical College Hospital.
- Frostbite: Functional and Morphologic Pathology and the Prevention of Subsequent Gangrene. KURT LANGE, M.D., DAVID WEINER, M.D., and LINN J. BOYD, M.D., New York. New York Medical College, Flower and Fifth Avenue Hospitals.
- The Right Heart Catheterization Technique as Applied to the Investigation of Arteriovenous Fistulas. A Case Study. B. W. HAYNES, JR., M.D., I. A. BIGGER, M.D., and EVERETT IDRIS EVANS, M.D., Richmond. Department of Surgery, Medical College of Virginia.
- Sympathectomy as an Adjunct in Surgery of Aneurysms and Arteriovenous Fistulas. HARRIS B. SHUMACKER, JR., M.D., New Haven. New Haven Hospital.
- The Use of Prolonged Continuous Spinal Anesthesia to Relieve Vasospasm and Pain in Peripheral Embolism. SCOTT M. SMITH, M.D., and VINCENT L. REES, M.D., Salt Lake City. University of Utah School of Medicine.
- Femoral Vein Ligation for Chronic Occlusive Arterial Disease. S. THOMAS GLASSER, M.D., New York. New York Medical College, Flower and Fifth Avenue Hospitals.
- The Effects of Altered Blood Flow in Venous Vasa Vasorum upon the Condition of Venous Endothelium, and the Relation of Anoxia of Vein Walls to Intravenous Thrombosis. JAMES F. O'NEILL, M.D., Boston. Department of Physiology, Harvard University School of Public Health.

Wednesday, 9:00 a.m.—Music Hall, Public Auditorium

MICHAEL L. MASON, M.D., Chicago, Presiding.

Wound Healing and Infection

- Experiments with Non-irritating Glove Powder. C. MARSHALL LEE, JR., M.D., Charlottesville. Department of Surgery and Gynecology, University of Virginia Department of Medicine.
- Magnesiogenous Pneumagranuloma as a Research Tool. CARL W. WALTER, M.D., Boston. Department of Surgery, Harvard Medical School—Peter Bent Brigham Hospital.
- Human Hemoglobin as a Vehicle. LIEUTENANT COLONEL FELIX JANSEY, M.C., A.U.S., Hines. Orthopedic Service, Veterans Administration Hospital, and Department of Surgery, Northwestern University Medical School.
- Rate of Gain in Strength in Sutured Abdominal Wounds. CLARENCE DENNIS, M.D., JOHN EAST, M.D., and CARLETON NELSON, M.D., Minneapolis. Department of Surgery, University of Minnesota Medical School.
- Clostridial Myositis. F. A. SIMEONE, M.D., Boston. Department of Surgery, Harvard Medical School—Massachusetts General Hospital.
- Results Following the Pigment Injection (Tattooing) of Port Wine Stains and Skin Grafts. HERBERT CONWAY, M.D., New York. New York Hospital.
- A New Operative Treatment of Elephantiasis. EDGAR J. POTH, M.D., and SAM R. BARNES, M.D., Galveston. University of Texas Medical Branch.
- Observations on the Volume of the Blood in Patients with Weight Loss. JOHN H. CLARK, M.D., New Orleans. Department of Surgery, Tulane University of Louisiana School of Medicine.
- The Estimation of Acute Blood Loss by the Tilt Test. DANIEL GREEN, M.D., and DAVID METHENY, M.D., Seattle. King County Hospital.
- Tissue Destruction in the Immediate Postoperative Period. ROBERT L. BERRY, M.D., VIVIAN JOE, Ph.D., and KENNETH N. CAMPBELL, M.D., Ann Arbor. Department of Surgery, University of Michigan Medical School.

The Diagnosis and Treatment of Fat Embolism. J. E. DONPHY, M.D., FREDERICK ILFELD, M.D., and MAGNUS SMEDAL, M.D., Boston. Department of Surgery, Harvard Medical School—Peter Bent Brigham Hospital.

Wednesday, 9:00 a.m.—Ballroom, Public Auditorium

ALEXANDER BRUNSCHWIG, M.D., Chicago, Presiding.

Liver, Gallbladder, and Pancreas

Intermittent External Biliary Drainage for Relief of Pruritus in Certain Chronic Disorders of the Liver. RICHARD L. VARCO, M.D., Minneapolis. Department of Surgery, University of Minnesota Medical School.

Visualization of Amebic Abscess of the Liver as an Aid to Therapy and Prognosis. HARRY C. HULL, M.D., Baltimore. University of Maryland School of Medicine and College of Physicians and Surgeons.

Experimental Implantations of the Common Bile Duct. TED BINKLEY, M.D., ROBERT PALMER, M.D., and H. J. MCCORKLE, M.D., San Francisco. Department of Experimental Surgery, University of California Medical School.

The Effect of Anemic Anoxia (Hemorrhage) and Anoxic Anoxia on Hepatic Function in Dogs. H. A. DAVIS, M.D., Los Angeles. Department of Surgery, College of Medical Evangelists.

Principles Involved in Surgical Therapy of "Encapsulated" Connective Tissue Malignancies. WALTER W. CARROLL, M.D., Chicago. Department of Surgery, Northwestern University Medical School.

Acute Pancreatitis and Its Sequelae. THOMAS J. ANGLE, M.D., Boston. Surgical Service, Massachusetts Memorial Hospitals; and Department of Surgery, Boston University School of Medicine.

Acute Pancreatitis: An Experimental Study with Special Reference to X-ray Therapy. TAGUE C. CHISHOLM, M.D., Minneapolis, and ROY E. SEIBEL, M.D., Boston. Department of Surgery, Harvard Medical School—Peter Bent Brigham Hospital.

Radical Pancreatoduodenectomy with Resection of the Patent Portal Vein. PAUL W. SCHAFER, M.D., Kansas City, Kansas. Department of Surgery, University of Kansas School of Medicine.

Pancreatic Reflux Deliberately Produced. HENRY DOUBILET, M.D., New York. New York University College of Medicine.

Care of the Dog with External Pancreatic Fistula. FRED KOLOUCH, M.D., Minneapolis. Department of Surgery, University of Minnesota Medical School.

Thursday, 9:00 a.m.—Music Hall, Public Auditorium

OWEN H. WANGENSTEEN, M.D., Minneapolis, Presiding.

Gastric Surgery

Carcinoma of the Stomach. CLAUDE E. WELCH, M.D., Boston. Department of Surgery, Harvard Medical School—Massachusetts General Hospital.

An Experimental Study of Motility of the Stomach after Vagotomy. RAYMOND W. POSTLETHWAIT, M.D., Durham, North Carolina. Department of Surgery, Duke University School of Medicine.

The Effect of Supradiaphragmatic Vagus Nerve Section in Man. WALTER B. CRANDELL, M.D., WALTER E. BOEHM, M.D., and JOHN H. MULHOLLAND, M.D., New York. New York University College of Medicine.

Complications Observed after Transthoracic Vagotomy for Peptic Ulcer. KEITH S. GRIMSON, M.D., Durham. Department of Surgery, Duke University School of Medicine.

The Condition of Eight Patients Fifteen Months or More After Total Gastrectomy. WILLIAM P. LONGMIRE, JR., M.D., Baltimore. Johns Hopkins University School of Medicine.

Use of Buffered Thrombin in Control of Gastric Hemorrhage. BYRNE M. DALY, M.D., Detroit. Departments of Surgery and Physiology, Wayne University College of Medicine.

The Sippy Regimen Protects Against the Histamine-provoked Ulcer. JOHN FAST, M.D., Minneapolis. Department of Surgery, University of Minnesota Medical School.

- Abetting Influence of Hemoconcentration on Ulcer Diathesis. IVAN D. BARONOFFSKY, M.B., Minneapolis. Department of Surgery, University of Minnesota Medical School.
- Autodigestion and Repair in the Normal and Hyperacid Canine Stomach. PHILIP B. PRICE, M.D., Salt Lake City. Department of Surgery, University of Utah School of Medicine.
- Experimental Burns Abet the Ulcer Diathesis. STANLEY R. FRIESEN, M.D., Minneapolis. Department of Surgery, University of Minnesota Medical School.
- A New Simplified Intestinal Decompression Tube. MEYER O. CANTOR, M. D., Detroit. Grace Hospital.

Thursday, 9:00 a.m.—Ballroom, Public Auditorium

HOWARD C. NAFFZIGER, M.D., San Francisco, Presiding.

Neurosurgery and Sympathectomy

- The Use of Penicillin in Conjunction with Bone Grafting in Experimental Skull Defects. H. J. MCCORMIE, M.D., ERWIN KERR, M.D., SANFORD ROTHENBERG, M.D., and HELEN WARNER, San Francisco. Department of Experimental Surgery, University of California Medical School.
- The Localization of Intracranial Tumors by Electroencephalography. R. C. BASSETT, M.D., and B. K. BAGCHI, Ph.D., Ann Arbor. University of Michigan Medical School.
- Decerebration in the Traumatized Human: Its Pathogenesis and Management. RUSSELL MEYERS, M.D., Iowa City. State University of Iowa College of Medicine.
- The Incidence of Interhemispheric Extension of Glioblastoma Multiforme Through the Corpus Callosum. HARRY P. MAXWELL, M.D., Milwaukee. Department of Surgery, Marquette University School of Medicine.
- After-image Perimetry. WILLIAM P. WILLIAMSON, M.D., Kansas City, Kansas. University of Kansas School of Medicine.
- Blockade of the Autonomic Ganglia by Tetra-ethyl Ammonium Bromide in Peripheral Vascular Disease and Causalgic States. KENNETH N. CAMPBELL, M.D., ROBERT L. BERRY, M.D., MARTIN R. SUTLER, M.D., RICHARD H. LYONS, M.D., and GORDON K. MOE, M.D., Ann Arbor. Department of Surgery, University of Michigan Medical School.
- The Effect of Autonomic Blockade on the Urinary Bladder in Man. JACK LAPIDES, M.D., REED M. NESBITT, M.D., WILLIAM L. VALE, M.D., MARTIN R. SUTLER, M.D., ROBERT L. BERRY, M.D., RICHARD H. LYONS, M.D., KENNETH N. CAMPBELL, M.D., and GORDON K. MOE, M.D., Ann Arbor. Department of Surgery, University of Michigan Medical School.
- Lumbar Ganglionectomy in Occlusive Peripheral Vascular Disease. GEORGE H. YEAGER, M.D., Baltimore. University of Maryland School of Medicine and College of Physicians and Surgeons.
- Testing Hypertensive Patients Preoperatively. JAMES L. SOUTHWORTH, M.D., Baltimore and HENRY I. RUSSEK, M.D., Staten Island. Surgical Service, United States Marine Hospital, Baltimore, and Cardiovascular Research Unit, United States Marine Hospital, Staten Island.
- The Operative and Postoperative Management of Hypertensive Patients Undergoing Thoracolumbar Sympathectomy. JERE W. LORD, JR., M.D., and J. WILLIAM HINTON, M.D., New York. Sympathectomy Clinic, New York Post-Graduate Medical School and Hospital.

Friday, 9:00 a.m.—Music Hall, Public Auditorium

GROVER C. PENBERTHY, M.D., Detroit, Presiding.

Extremities, Bones and Joints, Burns, and Gynecology.

- The Present Concepts Concerning the Care of the Burned Patient. WILLIAM E. ABBOTT, M.D., Detroit, and John Winslow Hirschfeld, M.D., Ithaca, New York. Harper Hospital, Detroit.
- The Physiological Approach to the Local Treatment of Burns. EDWARD L. HOWES, M.D., and WOLFGANG ACKERMANN, M.D., New York. Columbia University College of Physicians and Surgeons.
- Hypocholesterolemia of the Adrenal Glands in Experimental Burns. HENRY N. HARKINS, M.D., Baltimore. Johns Hopkins University School of Medicine.

- Disadvantages and Dangers of Refrigeration Anesthesia. KENNETH PEACOCK, M.D., and GUISEPPE D'ANDREA, M.D., New York. New York Medical College, Flower and Fifth Avenue Hospitals.
- The Problem of Pain in Amputation Stumps. LOUIS G. HERMANN, M.D., Cincinnati. University of Cincinnati College of Medicine.
- Immobilization of the Injured Hand in Position of Function. HARVEY S. ALLEN, M.D., Chicago. Department of Surgery, Northwestern University Medical School.
- Experimental Study of Internal Fixation of Fractures. WILLIAM H. AINSWORTH, M.D., Galveston. Department of Surgery, University of Texas Medical Branch.
- Acromioclavicular Separation. A Study of the End Results Obtained with the Screw Method of Repair. BOARDMAN M. BOSWORTH, M.D., New York. New York Hospital.
- Musculotendinous Tears of the Shoulder Joint. GEORGE E. WILSON, M.B., Toronto. University of Toronto Faculty of Medicine and St. Michael's Hospital.
- Diagnosis of Precancer of the Cervix by Cytology. J. ERNEST AYRE, M.D., Montreal. Gynecology Laboratory, Royal Victoria Hospital; and McGill University Faculty of Medicine.
- Modification in Technique of the Manchester Operation for Uterine Prolapse. RALPH E. CAMPBELL, M.D., Madison. University of Wisconsin Medical School.
- Extraperitoneal Iliac Lymphadenectomy in the Treatment of Cancer of the Cervix. IRA T. NATHANSON, M.D., Boston. Harvard Medical School—Massachusetts General Hospital, Tumor Clinic, Boston; and Pondville Hospital, Walpole.
- Endometriosis of the Gastrointestinal Tract. MARTIN R. SUTLER, M.D., Ann Arbor. Departments of Pathology and Surgery, University of Michigan Medical School.

Friday, 9:00 a.m.—Ballroom, Public Auditorium

CLAUDE S. BECK, M.D., Cleveland, Presiding.

Thorax, Breast, Heart, and Anesthesia

- Treatment of Chronic Non-tuberculous Pulmonary Abscesses. HARRY E. NELSON, M.D., Dallas. Southwestern Medical College of the Southwestern Medical Foundation.
- Surgical Treatment of Bullous Emphysema. JEROME R. HEAD, M.D., Chicago. Department of Surgery, Northwestern University Medical School.
- Anomalies of the Pulmonary Vein. O. C. BRANTIGAN, M.D., Baltimore. University of Maryland School of Medicine and College of Physicians and Surgeons.
- Physiological Studies in Congenital Heart Disease. RICHARD J. BING, M.D., and L. D. VANDAM, M.D., Baltimore. Department of Surgery, Johns Hopkins University School of Medicine.
- Experimental Aortic Valvulotomy: A Preliminary Report. H. G. SMITHY, M.D., and EDWARD F. PARKER, M.D., Charleston, South Carolina. Department of Surgery, Medical College of the State of South Carolina.
- Indications for Simple Mastectomy. DANIEL P. SLAUGHTER, M.D., and LAWRENCE W. PETERSON, M.D., Chicago. Tumor Clinic, Research and Educational Hospitals, University of Illinois College of Medicine.
- A Clinical Experimental Study of the Uptake of Radioactivated Phosphorus by Tumors of the Breast. B. V. A. LOW-BEER, M.D., H. GLENN BELL, M.D., H. J. MCCORKLE, M.D., and ROBERT S. STONE, M.D., with the assistance of W. B. HILL, M.D., and H. L. STEINBACH, M.D., San Francisco. Divisions of Radiology and Surgery, University of California Medical School.
- A New Type of Endobronchial Airway. C. P. BAILEY, M.D., and HENRY S. RUTH, M.D., Philadelphia. Departments of Surgery and Anesthesiology, Hahnemann Medical College and Hospital of Philadelphia.

TWENTY-FIFTH ANNUAL HOSPITAL STANDARDIZATION CONFERENCE

*Monday, 9:30 a.m.—Music Hall,
Public Auditorium*

Opening Session of Clinical Congress—General Assembly
W. EDWARD GALLIE, M.D., Toronto; President, American College of Surgeons, Presiding
Greetings from the American Hospital Association
JOHN H. HAYES, New York; President
Greetings from the Canadian Hospital Council
HARVEY AGNEW, M.D., Toronto; Secretary
Preliminary Statement, W. EDWARD GALLIE, M.D., Toronto.

Presentation of Report of Field Activities of the American College of Surgeons for 1946, and Summary of 28 Years of Hospital Standardization.

IRVIN ANELL, M.D., Louisville; Chairman, Board of Regents, American College of Surgeons.

Maintaining our Voluntary Hospital System
RIGHT REVEREND MONSIGNOR MAURICE T. GRIFFIN, Cleveland

Pertinent Findings from the National Survey by the Commission on Hospital Care.

ARTHUR C. BACHMEYER, M.D., Chicago; Director of Study, Commission on Hospital Care, Director, University of Chicago Clinics.

The Nursing Problem.

The Viewpoint of the Surgeon
HOWARD C. NAFZIGER, M.D., San Francisco; Professor of Surgery, University of California Medical School; Chairman, Committee on Nursing, American Surgical Association.

The Viewpoint of the Administrator.
ROBIN C. BUECKI, M.D., Philadelphia; Director, University Hospitals and Dean of the Graduate School of Medicine, University of Pennsylvania.

The Viewpoint of the Nurse.
LUCILE PETRY, R.N., Washington, Chief of the Division of Nursing, United States Public Health Service.

Monday, 2:00 p.m.—Ballroom, Public Auditorium

Panel Discussion on Current Problems and Immediate Future Outlook in Nursing Service.

Conducted by JOHN H. HAYES, New York; President, American Hospital Association, Superintendent, Lenox Hill Hospital.

The Future of Nursing
JAMES W. STEPHAN, Canton, Ohio; Director, Aultman Hospital.

Nursing Standards as Affected by Personnel Policies.
EDGAR BLAKE, JR., Chicago; Superintendent, Wesley Memorial Hospital

Postwar Student Nurse Recruitment Problems.
EDITH H. SMITH, Syracuse; Dean of the School of Nursing, Syracuse University.

The Training of a Secondary Group for Nursing Service.
H. LENORE BRADLEY, Albany; Supervisor of Nursing Education, New York Board of Nurse Examiners.

Round Table Conference on Nursing Problems.
Moderator: JAMES W. STEPHAN, Canton.

Collaborators:
PAUL H. FISLER, Oklahoma City; Administrator, University of Oklahoma Hospitals.

LOIS HOLIMAN, R.N., Chicago; Associate Director, Cook County School of Nursing.

CELLA CRANZ, R.N., Akron; Director of Nursing, City Hospital of Akron.

LFE S. LAMPHI R, Cleveland; Administrator, Lutheran Hospital.

HARVEY AGNEW, M.D., Toronto; Secretary, Canadian Hospital Council.

*Tuesday, 9:30 a.m.—Club Room B,
Public Auditorium*

Panel Discussion—The Securing of Complete and Scientific Medical Records.

Conducted by EVERETT W. JONES, Chicago; Vice-President, The Modern Hospital Publishing Company.

Introductory Remarks by the Chairman—Status of Medical Records in Hospitals as I Have Observed Them

The Program of the American Association of Medical Record Librarians to Improve Medical Record Science

LONA K. HUFFMAN, Chicago; Chief Medical Record Librarian, Wesley Memorial Hospital; Director, Program in Medical Record Library Science, Northwestern University.

The Importance of Complete and Scientific Medical Records from the Standpoints of:

Better Care of the Patient.

GILSON C. ENGEL, M.D., Philadelphia; Associate Professor of Surgery, University of Pennsylvania Graduate School of Medicine.

Self Education of the Practicing Physician.

JOHN K. ORNDORFF, M.D., Chicago; Clinical Assistant in Surgery, Northwestern University Medical School

Education and Training of Interns and Residents

FRODE JENSEN, M.D., Chicago; Council on Medical Education and Hospitals, American Medical Association

Advancement of Medical Science.

BRIGADIER-GENERAL WALLACE H. GRABAM, Washington; Physician to the President of the United States

Round Table Conference. The Problems Relating to the Obtaining of Complete and Scientific Medical Records

Moderator: EVERETT W. JONES, Chicago.

Collaborators—(In addition to Panel participants)

FRANK C. SUTTON, M.D., Rochester; Assistant Medical Director, Rochester General Hospital

WILLIAM B. SELTZER, Cleveland; Superintendent, Mount Sinai Hospital.

L. J. CROZIER, M.D., London; Superintendent, Victoria Hospital.

GUY W. BRUGLER, M.D., Cleveland; Assistant Director, University Hospitals.

HELEN L. POTTS, R.N., Woodstock, Ontario; Administrator, Woodstock General Hospital.

*Tuesday, 2:00 p.m.—Club Room B,
Public Auditorium*

Panel Discussion: Extending General Hospital Service to all Types of Patients.

HERMAN SMITH, M.D., Chicago; Hospital Consultant; President

Trends in the Care of Psychiatric Patients.

BOWMAN C. CROWELL, M.D., Chicago; Associate Director.

Types of Cases Referred to the Judiciary Committees.

MALCOLM T. MACEACHERN, M.D., Chicago; Associate Director.

Discussion by Regents and Fellows of the College.

PRELIMINARY CLINICAL PROGRAM

CLEVELAND CITY HOSPITAL

Tuesday

General Surgery

- S. O. FREEDLANDER, D. M. GLOVER, W. C. MCCALLY, M. B. TALIAK, J. H. LAZZARI, C. A. HAMANN, R. J. MCNAMEE, M. H. LAMBRIGHT, J. S. GELLER, A. M. LEIGH.
9:00 a.m.—Operative clinic.

Tumor Surgery

- L. A. POMEROY, S. O. FREEDLANDER, H. H. HAUSER, J. H. LAZZARI, A. E. BENNETT, and staff.
2:00 p.m.—Tumor clinic. Case presentations for diagnosis and treatment.

Pathology

- H. T. KARSNER, H. G. SCHLUMBERGER, R. C. TAYLOR, and staff.
2:00 p.m.—Clinical pathological conference.

Fractures and other traumas

- F. M. BARRY, D. DIAL, and staff.
2:00 p.m.—Fracture service; ward rounds; discussions of treatment and results.

Thoracic Surgery

- S. O. FREEDLANDER, R. C. MCKAY, M. C. PERLICH, C. W. MUNZ, D. B. KAY, and staff.
2:00 p.m.—Group conference. Selection of cases for thoracoplasty, lobectomy, and pneumonectomy.

Wednesday

General Surgery

- S. O. FREEDLANDER, D. M. GLOVER, W. C. MCCALLY, M. B. TALIAK, J. H. LAZZARI, C. A. HAMANN, R. J. MCNAMEE, M. H. LAMBRIGHT, J. S. GELLER, A. M. LEIGH.
9:00 a.m.—Operative clinic.
2:00 p.m.—Nonoperative clinic:
M. H. LAMBRIGHT. The acute abdomen in patients carrying artificial pneumoperitoneum.
J. S. GELLER. Acute obstructive cholecystitis.
A. M. LEIGH. Esophageal diverticula.
W. C. MCCALLY. Vagus nerve resection for peptic ulcer.
J. H. LAZZARI. Hemipelvectomy for sarcoma of femur.

Plastic Surgery

- D. M. GLOVER and C. A. HAMANN.
9:00 a.m.—Operative clinic.
2:00 p.m.—Nonoperative clinic; case presentations—problems and management of skin flaps. Lantern slides.

Otolaryngology

- C. W. ENGLER, W. F. HULSE, S. E. MISSAL, CRAMER and Associates.
9:00 a.m.—Operative clinic.
2:00 p.m.—Nonoperative clinic; demonstration of oral and laryngeal malignancies.

Thursday

Neurosurgery

- C. S. BECK, C. W. ELKINS, and associates.
9:00 a.m.—Operative clinic.
2:00 p.m.—Nonoperative clinic.
2:00 p.m.—C. W. ELKINS—Acrylic plastics in skull defects.

Vascular Surgery

- L. A. ATLAS and associates.
9:00 a.m.—Operative clinic; lumbar sympathectomy; saphenous vein ligations.
2:00 p.m.—Nonoperative clinic; demonstration of venograms; indications for femoral vein ligations.

Genitourinary Surgery

- H. R. TRATTNER, A. ROH, and associates.
9:00 a.m.—Operative clinic.

General Surgery

- R. W. SCOTT, S. O. FREEDLANDER, M. H. LAMBRIGHT, E. CHESTER, D. M. GLOVER, M. B. TALIAK, A. M. MARSHALL, J. H. LAZZARI, H. HOELSCHER, A. S. BROGLIO.
2:00 p.m.—Nonoperative clinic; lesions of stomach and intestine; pancreatic lithiasis with steatorrhea.

Friday

Thoracic Surgery

- S. O. FREEDLANDER, D. B. KAY, C. W. MUNZ, and associates.
9:00 a.m.—Operative clinic: pneumonectomy, lobectomy, thoracoplasty.
2:00 p.m.—Nonoperative clinic.
2:00 p.m.—Motion pictures: esophagectomy, pneumonectomy, lobectomy.

Orthopedic Surgery

- L. M. STARIN, A. TRAMER, P. H. DUBAY, and associates.
9:00 a.m.—Operative clinic: Spinal fusion.
9:00 a.m.—Nonoperative clinic.

Gynecology

- J. L. REYCRAFT, A. F. BENNETT, E. RICHARDS, and associates.
9:00 a.m.—Operative clinic: Plastics; vaginal hysterectomy; Watkin's interposition.

Radiology

- HARRY HAUSER and associates.
9:00 a.m.—A. R. COHEN—Roentgen diagnosis of lesions of small intestine.
10:00 a.m.—H. HAUSER—Roentgen diagnosis of thoracic tumors.
11:00 a.m.—H. BROWN—Differential roentgen diagnosis of mechanical and adynamic ileus.

CLEVELAND CLINIC

Tuesday

General Surgery

- T. E. JONES and GEORGE CRILE, JR.
8:00 a.m.—Operative surgery and demonstration of cases.
- R. L. HADEN, L. W. DIGGS, D. W. BORTZ and R. S. DINSMORE.
9:00 a.m.—Symposium—spleen: General considerations; platelets in hemorrhagic disease; presentation of cases; surgical aspects.
- IRVINE H. PAGE, Leader; A. C. CORCORAN, ROBERT D. TAYLOR and W. JAMES GARDNER.
11:00 a.m.—Symposium—hypertension: General considerations; selection of cases for surgery; surgical aspects.

Genitourinary Surgery

- CHARLES C. HIGGINS.
8:00 a.m.—Operative clinic.

Ophthalmology

- A. D. RUEDEMANN.
8:00 a.m.—Operative clinic.

Orthopedic Surgery

- JAMES A. DICKSON and J. I. KENDRICK.
8:30 a.m.—Operative clinic.

Otolaryngology

- PAUL M. MOORE, JR.
10:00 a.m.—Operative clinic.
- H. E. HARRIS.
1:00 p.m.—Operative clinic.

Pathology

- JOHN B. HAZARD.
10:00 a.m.—Surgical pathological conference.
- JOHN B. HAZARD.
11:45 a.m.—Demonstration of surgical pathological specimens.

Neurosurgery

- W. JAMES GARDNER, A. T. BUNTS, and W. A. NOSIK.
1:00 p.m.—Operative clinic.

Wednesday

General Surgery

- T. E. JONES.
8:00 a.m.—Operative clinic.
- GEORGE CRILE, JR., Leader; E. N. COLLINS, JOHN F. RENSHAV, J. C. ROOT, and HAROLD R. ROSSMILLER.
9:00 a.m.—Symposium: Upper stomach and pancreas.
- R. S. DINSMORE.
1:30 p.m.—Operative clinic.

Genitourinary Surgery

- CHARLES C. HIGGINS.
8:00 a.m.—Operative clinic.
- W. E. LOWER, CHARLES C. HIGGINS, W. J. ENGEL.
10:00 a.m.—Genitourinary clinic: Presentation of cases and discussion.
- T. E. JONES and associates.
11:00 a.m.—Clinic: Diseases of colon.

Ophthalmology

- A. D. RUEDEMANN and R. J. KENNEDY.
8:00 a.m.—Demonstration of cases.

Otolaryngology

- PAUL M. MOORE, JR.
10:00 a.m.—Operative clinic and demonstration of cases.

Pathology

- JOHN B. HAZARD.
11:45 a.m.—Demonstration of surgical pathological specimens.

Neurosurgery

- W. JAMES GARDNER, A. T. BUNTS and W. A. NOSIK.
1:00 p.m.—Operative clinics.

Thursday

General Surgery

- T. E. JONES and GEORGE CRILE, JR.
8:00 a.m.—Operative clinics.
- IRVINE H. PAGE, Leader; A. C. CORCORAN, ROBERT D. TAYLOR, and W. JAMES GARDNER.
11:00 a.m.—Symposium—Hypertension: General considerations; selection of cases for surgery; surgical aspects.

Genitourinary Surgery

- CHARLES C. HIGGINS.
8:00 a.m.—Operative clinic.
- WILLIAM J. ENGEL.
1:00 p.m.—Operative clinic and demonstration of cases.

Ophthalmology

- A. D. RUEDEMANN and R. J. KENNEDY.
8:00 a.m.—Operative clinic.

Orthopedic Surgery

- JAMES A. DICKSON and J. I. KENDRICK.
8:30 a.m.—Operative clinic.
- JAMES A. DICKSON, Leader; J. I. KENDRICK, and DR. PHALEN.
10:00 a.m.—Clinic—Hip Joint.

Otolaryngology

- PAUL M. MOORE, JR.
10:00 a.m.—Operative clinic.
- H. E. HARRIS.
1:00 p.m.—Operative clinic.

Pathology

- JOHN B. HAZARD.
11:45 a.m.—Demonstration of surgical pathological specimens.

Neurosurgery

- W. JAMES GARDNER, Leader; A. T. BUNTS, W. A. NOSIK, and A. STOWELL.
9:00 a.m.—Clinic: Presentation of cases and discussion.
- W. JAMES GARDNER, A. T. BUNTS, and W. A. NOSIK.
1:00 p.m.—Operative clinic.

Weekly Surgical Staff Conference

- 1:30 p.m.—Staff.

Friday

General Surgery

- T. E. JONES.
8:00 a.m.—Operative clinics.
- R. S. DINSMORE, E. PERRY McCULLAGH, GEORGE CRILE, Jr., and A. C. ERNSTENE.
9:00 a.m.—Thyroid clinic: Presentation of cases and discussion.
- DONALD B. HALE, U. V. PORTMANN, and HAROLD E. HARRIS.
10:00 a.m.—Discussion of special problems: Safeguards in spinal anesthesia; radiation therapy in carcinoma of breast; treatment of esophageal varices.
- IRVINE H. PAGE, Leader; A. C. CORCORAN, OTTO GLASSER, and W. JAMES GARDNER.
11:00 a.m.—Symposium—Shock: Crush syndrome; intra-arterial transfusions; induced hypotension.
- R. S. DINSMORE.
1:30 p.m.—Operative clinic.

Genitourinary Surgery

- CHARLES C. HIGGINS.
8:00 a.m.—Operative clinic.

Ophthalmology

- A. D. RUEDELMANN, and R. J. KENNEDY.
8:00 a.m.—Operative clinic.

Orthopedic Surgery

- JAMES A. DICKSON, and J. I. KENDRICK.
8:30 a.m.—Operative clinic.

Otolaryngology

- PAUL M. MOORE, JR.
10:00 a.m.—Operative clinic.

Pathology

- JOHN B. HAZARD.
11:45 a.m.—Demonstration of surgical pathological specimens.

Neurosurgery

- W. JAMES GARDNER, A. T. BUNTS, and W. A. NOSIK.
1:00 p.m.—Operative clinic.

EVANGELICAL DEACONESS HOSPITAL

Wednesday

General Surgery

- J. R. JOHNSON and associates.
9:00 a.m.—Operative and nonoperative clinic.

Thursday

General Surgery

- O. A. WEBER and associates.
9:00 a.m.—Operative and nonoperative clinic.

Friday

General Surgery

- S. C. LIND and associates.
9:00 a.m.—Operative and nonoperative clinic.

FAIRVIEW PARK HOSPITAL

Tuesday

General Surgery

- W. E. SMITH and F. H. HEYSE.
9:00 a.m.—Operative clinic.

Obstetrics and Gynecology

- E. D. SAUNDERS.
9:00 a.m.—Operative clinic.

Wednesday

General Surgery

- H. W. MASENHIMER and J. R. KELKER.
9:00 a.m.—Operative clinic.

Genitourinary Surgery

- L. F. HUFFMAN.
9:00 a.m.—Operative clinic.

Thursday

Orthopedic Surgery

- G. I. BAUMAN.
9:00 a.m.—Operative clinic.

Roentgenology

- E. V. BAEYER.
9:00 a.m.—Demonstration of films.

Obstetrics and Gynecology

- E. D. SAUNDERS.
2:00 p.m.—Nonoperative clinic.

Friday

General Surgery

- H. W. MASENHIMER, W. E. SMITH, J. R. KELKER, and F. H. J. HEYSE.
9:00 a.m.—Operative clinic.

Otolaryngology

- W. H. RIEGER.
2:00 p.m.—Operative clinic.

GRACE HOSPITAL

Tuesday

Obstetrics and Gynecology

- PAUL F. HASSE.
2:00 p.m.—Operative clinic.

Ophthalmology and Otolaryngology

- H. W. COOPER.
2:00 p.m.—Operative clinic.

Wednesday

General Surgery

- HARRY C. BARR.
9:00 a.m.—Operative and nonoperative clinic, rectal.
- A. E. BIDDINGER.
2:00 p.m.—Operative clinic.

Orthopedic Surgery

LOUIS M. STARIN and PAUL H. DUBE.
9:00 a.m.—Operative and nonoperative clinic.

Otolaryngology

FORREST W. MERICA.
2:00 p.m.—Nonoperative clinic: Vertigo due to eustachian tube obstruction and its treatment.

Thursday

General Surgery

NORTH W. SHITTER.
9:00 a.m.—Exhibit of interesting x-ray cases; discussion of radiological problems.
STANLEY N. F. DEVILLE and G. C. RANKIN.
9:00 a.m.—Demonstration of technique of spinal anesthesia.

Otolaryngology

RALPH W. FRACKELTON.
9:00 a.m.—Operations: Nasal plastic.
Staff.
2:00 p.m.—Nonoperative clinic: Peroral endoscopy.

LUTHERAN HOSPITAL

Tuesday

General Surgery

D. S. SPRING, J. H. LAZZARI, F. A. CATALANO, W. R. HODGES, II, H. ROENICK, L. R. HEXTER.
9:00 a.m.—Operative clinic.
J. P. EICHMORN, J. A. GROH, and H. G. SLOAN.
10:00 a.m.—Nonoperative clinic—Symposium on peptic ulcer: Medical aspects, radiological aspects; surgical aspects.

Wednesday

General Surgery

H. G. SLOAN, B. B. LARSEN, V. L. TICNY, J. H. TILDES, E. C. ROY, J. F. HATTENBACH.
9:00 a.m.—Operative clinic.
Staff—J. H. LAZZARI, Chairman.
10:30 a.m.—Tumor clinic—Presentation of current cases

Thursday

General Surgery

F. S. GIBSON, J. T. BOHM, G. A. TISCHLER, C. E. WARD, C. F. WARD, CONRAD OTTELIN, C. W. HARRIS.
9:00 a.m.—Operative clinic.
F. S. GIBSON, FRANCIS BAYLESS, and J. A. GROH.
10:30 a.m.—Nonoperative clinic: Symposium on diseases of the breast: The clinical diagnosis; pathology of breast tumors, the value of x-ray as a postoperative agent.

Friday

General Surgery

S. C. LIND, J. H. LAZZARI, I. J. GOODMAN, B. B. LARSEN, D. S. SPRING.
9:00 a.m.—Operative clinic.

Ophthalmology

W. P. CHAMBERLAIN, JR.
9:00 a.m.—Operative clinic.

Genitourinary Surgery

D. A. CHAMBERS and W. E. FORSYTHE.
9:00 a.m.—Operative clinic.

THE POLYCLINIC HOSPITAL

Tuesday

General Surgery

HENRY A. SCHLINK.
8:00 a.m.—Operative clinic.
JOHN R. FLENT.
10:00 a.m.—Operative clinic.

Obstetrics and Gynecology

WILLIAM N. MACEY.
11:00 a.m.—Operative clinic.

Wednesday

General Surgery

PAUL M. SPURNEY.
9:00 a.m.—Operative clinic.
WILLIAM KUTLER.
10:00 a.m.—Operative clinic.
CHARLES J. PROCHASKA.
11:00 a.m.—Operative clinic.

Fractures and Other Traumas

S. L. ROBBINS.
9:00 a.m.—Fracture clinic.

Genitourinary Surgery

HARRY R. TRATTNER.
9:00 a.m.—Nonoperative clinic: Prostatectomy.

Thursday

General Surgery

JOHN T. VITKUS.
9:00 a.m.—Operative clinic.
A. J. KAZLAUCKAS.
10:00 a.m.—Operative clinic.

Otolaryngology

A. L. STOTTER.
9:00 a.m.—Nasal reconstruction.

Pathology

Nonoperative clinic.
11:00 a.m.—Clinical pathological conference.

Friday

Nonoperative clinic.
9:00 a.m.—Carcinoma, corpus uteri; spontaneous rupture of uterus; intestinal obstruction; ectopic gestation.

MACDONALD HOUSE—UNIVERSITY HOSPITALS

Tuesday

Gynecology and Obstetrics

J. L. REYCRRAFT,
9:30 a.m.—Gynecology operative clinic.
W. R. BARNEY.
11:00 a.m.—Ward rounds.

Wednesday

Gynecology and Obstetrics

- R. L. FAULKNER.
9:30 a.m.—Symposium: Uterine bleeding.
L. A. POMEROY.
11:00 a.m.—Carcinoma cervix.

Thursday

Gynecology and Obstetrics

- R. L. FAULKNER.
9:30 a.m.—Obstetrics and gynecology pathological conference.
R. A. SHIPLEY.
11:00 a.m.—Presentation of gynecological endocrine problems.

MOUNT SINAI HOSPITAL

Tuesday

Orthopedic Surgery

- RUDOLPH S. REICH, A. MILLER, A. W. TRAMER, S. KLEIN,
A. H. DRIELS.
8:00 a.m.—Operative clinic.

Obstetrics and Gynecology

- JACOB L. BUBIS and staff.
9:00 a.m.—Nonoperative clinic.

Oral Surgery

- EDWARD REITER.
2:00 p.m.—Nonoperative clinic.

Genitourinary Surgery

- D. SCHNITZER.
9:00 a.m.—Nonoperative clinic: Traumatic-urological complications of abdominal surgery.
J. GALVIN.
9:00 a.m.—Nonoperative clinic: Carcinoma of the ureter.
A. ROTH.
9:00 a.m.—Nonoperative clinic: Carcinoma of the kidney.

Wednesday

General Surgery

- S. O. FREEDLANDER, H. M. GANS, H. H. PEVAROFF, DR.
HOFFMAN, DR. GELLER, DR. BOOKATZ.
8:00 a.m.—Operative clinic.

Pathology

- B. J. KLINE and DR. YOUNG.
2:00 p.m.—Clinical pathology.

Ophthalmology

- H. M. GANS and staff.
2:00 p.m.—Nonoperative clinic: Ophthalmological problems illustrated with Kodachrome slides.

Otorhinolaryngology

- S. S. QUITTNER and S. BAUMOEL.
9:00 a.m.—Nonoperative clinic: Vertigo.

Thursday

Obstetrics and Gynecology

- JACOB L. BUBIS and staff.
8:00 a.m.—Operative clinic.

General Surgery

- S. O. FREEDLANDER and staff.
9:00 a.m.—Nonoperative clinic.

Pathology

- B. J. KLINE and DR. YOUNG.
2:00 p.m.—Pathological conference.

Friday

General Surgery

- S. O. FREEDLANDER and staff.
8:00 a.m.—Operative clinic.

Orthopedic Surgery

- RUDOLPH S. REICH and staff.
9:00 a.m.—Nonoperative clinic: End results of ununited fractures of the femoral neck; fractures of the elbow; fractures of the calcaneus; unreduced Pott's fractures.

ST. ALEXIS HOSPITAL

Tuesday

General Surgery

- J. F. CORRIGAN, W. F. BOUKALIK, E. F. KIEGER, E. A. MASTICS, F. A. SPITTLER, J. N. WYCHGEL.
9:00 a.m.—Operative clinic.

Genitourinary Surgery

- J. A. SOMMER and C. R. NUCKOLLS.
9:00 a.m.—Operative clinic.

Neurosurgery

- E. W. SHANNON.
9:00 a.m.—Operative clinic.

Ophthalmology

- H. V. PHELAN.
9:00 a.m.—Operative clinic.
10:00 a.m.—Demonstration of cases.

Otolaryngology

- F. W. DIXON and FRED ADELSTEIN.
9:00 a.m.—Operative clinic.

Wednesday

General Surgery

- J. F. CORRIGAN, W. F. BOUKALIK, E. F. KIEGER, E. A. MASTICS, F. A. SPITTLER, J. N. WYCHGEL.
9:00 a.m.—Operative clinic.

Genitourinary Surgery

- J. A. SOMMER and C. R. NUCKOLLS.
9:00 a.m.—Operative clinic.

Ophthalmology

- H. V. PHELAN.
9:00 a.m.—Operative clinic.

Thursday

General Surgery

- J. F. CORRIGAN, W. F. BOUKALIK, E. F. KIEGER, E. A. MASTICS, F. A. SPITTLER, J. N. WYCHGEL.
9:00 a.m.—Operative clinic.

Genitourinary Surgery

J. A. SOMMER and C. R. NUCKOLLS.
9:00 a.m.—Operative clinic.

Neurosurgery

E. W. SHANNON.
9:00 a.m.—Operative clinic.

Ophthalmology

H. V. PHELAN.
9:00 a.m.—Operative clinic.

Otolaryngology

F. W. DIXON and FRED ADELSTEIN.
9:00 a.m.—Operative clinic.

ST. JOHN'S HOSPITAL

Tuesday

General Surgery

J. R. RIFTON.
9:00 a.m.—Operative clinic: Thyroid surgery.
J. W. HANNIBAL.
9:00 a.m.—Operative clinic: Gall-bladder and common duct surgery.
WILLIAM NOVINE.
9:00 a.m.—Nonoperative clinic: Discussion of liver function tests.

Otolaryngology

J. T. COLLINS.
10:00 a.m.—Operative clinic: Radical antrum.

Neurosurgery

E. W. SHANNON.
10:00 a.m.—Operative clinic: Intervertebral disc.

Wednesday

General Surgery

J. R. RIFTON.
9:00 a.m.—Operative clinic: Gall bladder.
C. E. STEYER.
11:00 a.m.—Nonoperative clinic: liver and gall bladder.
WILLIAM E. MISHLER.
10:00 a.m.—Operative clinic: Hernia.

Genitourinary Surgery

J. A. SOMMER.
9:00 a.m.—Operative clinic: Nephrectomy.
WILLIAM J. MANNING.
10:00 a.m.—Nonoperative clinic: Indications for suprapubic prostatectomy.

Roentgenology

DAVID STEEL.
2:00 p.m.—Tumor clinic.
H. C. HARTZELL.
2:00 p.m.—Tumor clinic.

Thursday

General Surgery

F. T. GALLAGHER.
9:00 a.m.—Gastric resection (indications for Billroth No. 1 and Hoffmeister-Balfour resections).
J. E. HANNIBAL.
9:00 a.m.—Thyroid surgery.

Fractures and Other Traumas

R. J. SCHRAFF.
10:00 a.m.—Intracapsular fracture of neck of femur, Smith-Petersen nail.

Otolaryngology

F. L. MCGANNON.
10:00 a.m.—Nonoperative clinic: Hemangioma of uvula.

Thoracic Surgery

C. W. MUNZ.
11:00 a.m.—Operative clinic.

Friday

General Surgery

J. E. HANNIBAL.
9:00 a.m.—Carcinoma of the recto-sigmoid, anterior resection.
F. T. GALLAGHER.
9:00 a.m.—Combined abdomino-perineal resection.
R. J. SCHRAFF.
9:00 a.m.—Nonoperative clinic: Skin graft.
WILLIAM E. MISHLER.
11:00 a.m.—Nonoperative clinic: Injury to knee.

Otolaryngology

DAVID STEEL.
10:00 a.m.—Radiation in otolaryngology.

ST. LUKE'S HOSPITAL

Tuesday

General Surgery

D. M. GLOVER, R. S. MCGINNIS, and staff.
9:00 a.m.—Operative clinic.
B. B. SANKEY and staff.
9:00 a.m.—Demonstration in anesthesia.

Thoracic Surgery

EARLE B. KAY.
9:00 a.m.—Operative clinic.

Pathology

RAFAEL DOMINGUEZ and staff.
1:30 p.m.—Surgical pathological conference.

General Surgical Clinic

ERNEST F. BRIGHT.
2:30 p.m.—Peripheral vascular clinic.
R. S. MCGINNIS.
2:30 p.m.—Early ambulation in relation to postoperative complications.
HAROLD J. THEISEN.
3:10 p.m.—Amino acid therapy.
EDMUND E. BEARD.
3:20 p.m.—Thiourea in thyrotoxicosis.
JOHN A. TOPINKA.
3:30 p.m.—Work of the tissue committee.
JOHN H. NICHOLS.
4:00 p.m.—Psychic disorders simulating surgical conditions.
D. M. GLOVER.
4:20 p.m.—Wound management.
Discussion.
4:35 p.m.

Thoracic Surgical Clinic

- EARLE B. KAY.
2:30 p.m.—Pneumonectomies (motion pictures).
EARLE B. KAY.
2:50 p.m.—Esophageal resections for stricture.
A. D. NICHOL.
3:10 p.m.—Follow-up on patent ductus cases from the cardiac clinic.
Discussion.
3:40 p.m.

Wednesday

General Surgery

- B. B. SANKEY and staff.
9:00 a.m.—Demonstrations in anesthesia.

Neurosurgery

- SPENCER BRADEN.
9:00 a.m.—Operative clinic.
2:00 p.m.—Neurosurgical clinic:
SPENCER BRADEN.
2:00 p.m.—The herniated disc.
DON D. BRANNAN.
2:30 p.m.—Myelography.
F. R. HILL and SPENCER BRADEN.
2:50 p.m.—Management of head injuries
JOHN H. NICHOLS.
3:00 p.m.—The traumatic neurosis.

Orthopedic and Traumatic Surgery

- T. A. WILLIS and staff.
9:00 a.m.—Operative clinic.
3:30 p.m.—Orthopedic and traumatic surgery clinic:
T. A. WILLIS.
3:30 p.m.—Management of the fractured hip.
B. B. LARSEN.
3:50 p.m.—Fixation of the hip (motion pictures).
W. H. MCGAW.
4:10 p.m.—Internal derangements of the knee; pneumograms.
Discussion.
4:40 p.m.

Obstetrics and Gynecology

- C. T. HEMMINGS, G. B. HURD, and staff.
9:00 a.m.—Operative clinic.
2:00 p.m.—Obstetrical and gynecological clinic.
C. T. HEMMINGS.
2:00 p.m.—Conduct of normal delivery (motion pictures).
C. T. HEMMINGS.
2:30 p.m.—Operative obstetrics (motion pictures).
GERALD B. HURD.
3:00 p.m.—Management of uterine displacements.

Tumor Conference

- D. D. BRANNAN and R. DOMINGUEZ.
3:30 p.m.—Lymphoma.
L. A. POMEROY.
3:45 p.m.—Carcinoma of the cervix.
GERALD B. HURD.
4:00 p.m.—Carcinoma of the uterine body.
R. B. HERRICK.
4:15 p.m.—Bone tumors.
R. S. MCGINNIS.
4:30 p.m.—Carcinoma of stomach; carcinoma of colon.
P. J. ROBECHER.
4:45 p.m.—Carcinoma of the breast.

Thursday

General Surgery

- B. B. SANKEY and staff.
9:00 a.m.—Demonstrations in anesthesia.
2:00 p.m.—Clinic on anesthesiology.
G. R. HAMILTON.
2:00 p.m.—Supportive therapy in the operating room.
R. M. CRANT.
2:20 p.m.—Anesthesia in thyroid surgery.
L. E. CAMPBELL.
2:40 p.m.—Clinical aspects of curare.
B. B. SANKEY.
3:00 p.m.—Some aspects of spinal anesthesia.

Plastic and Maxillofacial Surgery

- D. M. GLOVER and D. T. SHAW.
9:00 a.m.—Operative clinic.
D. M. GLOVER, D. T. SHAW, C. A. HAMANN, and GAYLORD JAMES, D.D.S.
3:15 p.m.—Plastic and maxillofacial surgery clinic: operative management of the harelip (motion pictures); Cleft Palate Problems: surgery, speech training, prosthesis; various applications of split thickness grafts; pedicle grafts, hand problems; reconstruction of external ear, temporomandibular ankylosis.

Orthopedic and Traumatic Surgery

- T. A. WILLIS.
9:00 a.m.—Orthopedic and traumatic surgical operations.
WALLACE S. DUNCAN, T. A. WILLIS, W. A. ENGEL, D. M. GLOVER.
2:00 p.m.—Orthopedic and traumatic surgery clinic: Disabilities of the ankle joint; low back pain; 20 year review of burns.

Friday

General Surgery

- B. B. SANKEY and staff.
9:00 a.m.—Anesthesia demonstrations.
9:00 a.m.—General surgical clinic.
P. J. ROBECHER.
9:00 a.m.—Postoperative complications and deaths.
R. S. MCGINNIS.
9:15 a.m.—Intestinal obstruction.
B. B. LARSEN.
9:35 a.m.—The pilonidal sinus; operative treatment (motion pictures).
W. C. FARGO.
10:00 a.m.—Pyloric stenosis in the infant.
D. M. GLOVER.
10:20 a.m.—Anomalies of the intestinal tract in the newborn.
J. G. JONES.
10:45 a.m.—Biliary fistula—subphrenic abscess—bronchial fistula.
Discussion.
11:00 a.m.

Genitourinary Surgery

- C. A. BOWERS and staff.
9:00 a.m.—Urological operations.
2:00 p.m.—Urological clinic.
D. A. CHAMBERS.
2:00 p.m.—Nephrectomy in surgical hypertension.
H. B. WRIGHT.
2:30 p.m.—Treatment of vesicovaginal fistula.

JAMES LYNCH.

3:00 p.m.—Cysts of the kidney.

D. W. MCINTYRE.

3:30 p.m.—Discussion of renal tumors.

C. A. BOWERS.

4:00 p.m.—The present status of prostatic surgery.

Otorhinolaryngology

THOMAS W. THORBURN and staff

9:00 a.m.—Otorhinolaryngological operations.

2:00 p.m.—Otorhinolaryngological clinic.

J. W. MCCALL

2:00 p.m.—The esophageal voice in laryngectomized patients.

C. E. KINNEY.

2:30 p.m.—Results of the fenestration operation.

F. W. ALI VANDLER

3:00 p.m.—Common errors in rhinoplasty.

T. W. THORBURN

3:30 p.m.—Management of the nasal septum tip deflection in rhinoplasty

WARD MILLS

4:00 p.m.—Case of double malignancy of the larynx.

LEE STONER

4:15 p.m.—Esophageal stricture due to lye ingestion, complicated by peri-esophageal metastases of a supranal tumor.

Ophthalmology

M. W. JACOBY and staff.

9:00 a.m.—Ophthalmological clinic.

PAUL G. MOORE

9:00 a.m.—Traumatic eye surgery; intraocular foreign bodies.

M. W. JACOBY

9:30 a.m.—Traumatic eye surgery: contusions of globe, intraocular hemorrhage and secondary glaucoma.

Discussion.

10:00 a.m.

GERALD T. SCHWARZ and M. I. SPARKS.

10:15 a.m.—The albumin-globulin ratio: its relation to diabetic retinopathy.

B. J. WOLPAW.

10:45 a.m.—Visual requirements for flying (original study, Naval Flying School, Pensacola).

Discussion.

11:15 a.m.

E. F. HARVEY.

11:30 a.m.—Interesting fundus cases: a. Pits of optic nerve; b. Division of optic nerve with extensive field defect; c. Angioid streaks of retina.

Discussion.

12:00 noon.

ST. VINCENT CHARITY HOSPITAL

Tuesday

Ophthalmology

H. H. WYAND and associates.

2:00 p.m.—Nonoperative clinic.

Wednesday

General Surgery

O. A. WEBER and associates.

9:00 a.m.—Operative clinic.

Orthopedic Surgery

C. G. BARBER and associates.

9:00 a.m.—Operative clinic.

Thursday

General Surgery

Tumor clinic.

8:00 a.m.

J. E. HALLISY and associates.

9:00 a.m.—Operative clinic.

Otolaryngology

C. W. ENGLER and associates.

9:00 a.m.—Operative clinic.

Friday

General Surgery

E. P. NEARA and associates.

9:00 a.m.—Operative clinic.

Genitourinary Surgery

H. R. TRATNER, L. F. HUFFMAN, and H. R. WRIGHT.

9:00 a.m.—Operative clinic.

UNITED STATES MARINE HOSPITAL

Tuesday

Genitourinary Surgery

D. W. MCINTYRE.

9:00 a.m.—Clinic, followed by operations

Orthopedic Surgery

T. A. WILLIS.

9:00 a.m.—Nonoperative clinic.

CRILE VETERANS ADMINISTRATION HOSPITAL

Tuesday

WILBERT H. MCGAW, DONALD L. DIAL, N. W. TIMMESSEN, and VERNON L. TICHY.

9:00 a.m.—Operative clinic.

WILBERT H. MCGAW.

2:00 p.m.—Presentation of Orthopedic Cases

Wednesday

WILLIAM C. MCCALLY, CLAUDE S. BECK, JOHN J. THORNTON, and DARRELL T. SHAW.

9:00 a.m.—Operative clinic.

WILLIAM C. MCCALLY.

2:00 p.m.—Selection of Cases for Vagotomy.

Thursday

EARLE B. KAY, PHILIP F. PARTINGTON, and CYRIL T. SURINGTON.

9:00 a.m.—Operative clinic.

PHILIP F. PARTINGTON.

2:00 p.m.—Cholangiography as a Diagnostic Aid.

VERNON L. TICHY.

2:00 p.m.—Difficulty in Diagnosis of Regional Enteritis.

SURGERY GYNECOLOGY AND OBSTETRICS

SUBJECT INDEX TO VOLUME 83

ABDOMEN, Technique for repair of postoperative abdominal hernias, 200; Continuity of fasciae lining, pelvis, and spermatic cord, 575; Primary retroperitoneal tumors, report of 95 cases and review of literature, 705
Abnormalities, Surgical significance of aortic arch, 435; Malformation of anus and rectum, 499

American College of Surgeons—

Clinical Congress, Program for 1946, in New York September 9 to 13, 1946, 139; in New York postponed because of United Nations Assembly, 267; to be held in Cleveland December 16 to 20, 409; Preliminary program for 1946, in Cleveland December 16 to 20, 553; 680; 821

Amputation, forearm, Cineplastic, and prostheses, 373; Surgical treatment of gangrene in trench foot, 513; Vascular injuries in war, 667

Anastomosis, esophagogastric, Subtotal esophagectomy with high intrathoracic, in treatment of extensive electrical obliteration of esophagus, 417

Anesthesia, surgical, Evaluation of certain drugs used to maintain blood pressure during spinal anesthesia, comparison of ephedrine, parendrine, pitressin-ephedrine, and methedrine in 2500 cases, 312

Aneurysm, Arteriovenous fistulas of cervical portion of vertebral vessels, 625

Anomalies, see abnormalities

Anticoagulants, Effect of, on postpartum bleeding, 528

Anus, Malformation of, and rectum, 499

Aortic arch, Surgical significance of, anomalies, 435

Appendicitis, in Cleveland, final report, 613

Appendix, Peritonitis of appendiceal origin treated with massive doses of penicillin, report of 50 cases, 150; Appendicitis in Cleveland, final report, 613

Arteries, Surgical significance of aortic arch anomalies, 435; Vascular injuries in war, 667

BILE ducts, Reconstructive operations for benign stricture of, 24; common, Surgical treatment of acute cholecystitis, 50; common, Effects of certain drugs on sphincter of Oddi, 210; Benign strictures of, ed. 549
Biliary tract, Suppurative cholangitis complicating side-tracking operations of, 428

Bladder, Repair of vesicovaginal fistula caused by radiation, 348; Cherney incision as applied to surgery of lower ureter and, 364; cord, Transurethral resection in surgical management of, 597

Bleeding, postpartum, Effect of anticoagulants on, 528

Blood, Experimental study on liver function tests, 171; circulation, Effect of pulmonary resuscitative procedures upon, as demonstrated by use of radioactive sodium, 387; clotting of, Absorbable hemostatic agents, ed. 403; Rh factor-serologic background and clinical application—correction, cor. 408; Malaria and transfusions, ed. 674

Blood pressure, Evaluation of certain drugs used to maintain, during spinal anesthesia, comparison of ephedrine, parendrine, pitressin-ephedrine and methedrine in 2500 cases, 312

Blood vessels, thoracic, Foreign bodies in, and in relation to, and heart, I. Techniques for approaching and removing foreign bodies from chambers of heart, 117; Surgical significance of aortic arch anomalies, 435; Thrombophlebitis of deep veins in thromboangitis obliterans, 449; vertebral, Arteriovenous fistulas of cervical portion of, 625

Bone, grafts, Use of penicillin therapy in conjunction with free, in infected areas, 101; grafts, Cancellous, for infected, defects, single stage procedure, 392; Management of osteomyelitis secondary to war wounds, 507; defects, Reconstruction of, of face, with special reference to cancellous iliac, 761

Breast, Liposarcoma of female mammary gland, 216; Diagnosis and therapeutic of simple cysts of, 239, Unusual manifestations of, carcinoma, I. Metastasis to mandible with report of 5 cases, 289; cancer, 205 cases of, treated by radical mastectomy, 751

Burns, Severe, clinical findings with simplified plan of early treatment, 187; Protein nutrition of surgical patients, ed. 259

CANCER, of breast, Diagnosis and therapeutic of simple cysts of breast, 239, Gastric, laparotomy, resectability, and mortality, 480; of breast, 205 cases of, treated by radical mastectomy, 751

Cancer research, Surgery and cancer problem, ed. 129

Carcinoma, Unusual metastatic manifestations of breast, I. Metastasis to mandible with report of 5 cases, 289; gastric, Relative surgical curability of certain gross types of, 453; Gastric, incidence and diagnostic procedures, 572; of larynx, Further experiences with pan-laryngectomy for advanced, 639; of esophagus and stomach, Trans-thoracic operations for neoplasms, 657; of stomach, Perforated gastric malignancy, 718; of cardia and lower esophagus, Combined abdominothoracic approach for, 737, Combined jaw resection neck dissection for metastatic, of cervical lymph nodes secondarily involving mandible, 767

Cardia, Combined abdominothoracic approach for carcinoma of, and lower esophagus, 737

Case history, Plea for personal case record, ed. 130

Catgut, Study of absorption characteristics of surgical, 521

Causalgia, study of 75 cases, 789

Chemotherapy, Local, of wounds, tissue toxicity of certain antibacterial substances, 1

Chicago Lying-In Hospital, Management of placenta previa at, review of 325 cases during 1931 to 1945, 777

Cholangitis, Suppurative, complicating side-tracking operations of biliary tract, 428

Cholecystitis, Surgical treatment of acute, 50

Clavicle, Fractures of upper end and shaft of humerus, simple conservative method of treatment, 126

Clostridium welchii, Identification of, in mixed cultures and debrided tissue and determination of sensitivity of organism to penicillin, 343

Cooper, Sir Astley Paston, Continuity of fasciae lining abdomen, pelvis, and spermatic cord, 575

Cysts, pancreatic, Surgical treatment of, 181; Diagnosis and therapeutic of simple, of breast, 239

DEFICIENCY, dietary, Nutrition in pregnancy, effects of, in pregnancy and detection and treatment of nutritional, diseases, 561

Diagnosis, roentgenographic, Mandibular tumors, clinical, and histopathologic study, 355

Diarrhea, Protein nutrition of surgical patients, ed. 259

Diet, Nutrition in pregnancy, effects of dietary deficiency in pregnancy and detection and treatment of nutritional deficiency diseases, 561

Digestion, Gastric, of living tissue, 61

Disc, intervertebral, Bilateral and multiple ruptured discs as one cause of persistent symptoms following operation for herniated, 485; intervertebral, Treatment of painful spondylolisthesis, 797

Disease, nutritional deficiency, Nutrition in pregnancy, effects of dietary deficiency in pregnancy and detection and treatment of, 361

Drugs, adrenalin chloride, amyl nitrite, calcium chloride, 1/10 N hydrochloric acid, morphine sulfate, novocain, surgical putridin, Effects of certain, on sphincter of Oddi, 210, ephedrine, paredrine, pitressin ephedrine, methedrine, Evaluation of certain drugs used to maintain blood pressure during spinal anesthesia, comparison of, in 2500 cases, 312

Duodenum, Malignant lesions of, 83; Section of vagus nerves to stomach in treatment of peptic ulcer, ed. 547

ESOPHAGECTOMY, Subtotal, with high intrathoracic esophagogastric anastomosis in treatment of extensive cicatricial obliteration of esophagus, 417

Esophagus, Spontaneous rupture of, 234; Subtotal esophagectomy with high intrathoracic esophagogastric anastomosis in treatment of extensive cicatricial obliteration of, 417; Transthoracic operations for neoplasms of, and stomach, 657. Combined abdomino-thoracic approach for carcinoma of cardia and lower, 737

FACE, wounds, Management of plastic maxillofacial wounds in evacuation hospital, 462; Reconstruction of bony defects of, with special reference to cancellous iliac bone, 761

Fascia, ex, Fate of preserved heterogeneous grafts of, when transplanted into living human tissues, 145; Continuity of fasciae lining abdomen, pelvis, and spermatic cord, 575

Fatality rate, Appendicitis in Cleveland, final report, 613

Finger, index, Functional restoration of thumb, pollicization of, 807

Fistula, vesicovaginal, Repair of, caused by radiation, 348; biliary, Benign strictures of bile duct, ed. 549, Arterio-venous, of cervical portion of vertebral vessels, 625

Flap, median forehead, Repair of nasal defects with, primary closure of forehead wound, 37; muscle-fascia, Philonid sinus, treatment by primary closure, 94; tubed abdominal, One stage, single pedicle tubes, 205; Functional restoration of thumb, pollicization of index, 807

Foot, Surgical aspects of trench foot, 243; Surgical treatment of gangrene in trench, 513

Forearm, amputation, Cineplastic, and prostheses, 373

Forehead, Repair of nasal defects with median, flap, primary closure of, wound, 37

Foreign bodies, in, and in relation to, thoracic blood vessels and heart, I. Techniques for approaching and removing, from chambers of heart, 117

GALL bladder, Reconstructive operations for benign stricture of bile ducts, 24; Surgical treatment of acute cholecystitis, 30; Suppurative cholangitis complicating sidetracking operations of biliary tract, 428

Gangrene, Surgical aspects of trench foot, 243; Surgical treatment of, in trench foot, 513

Goiter, exophthalmic, Thyroauril will not replace thyroidectomy, 249

Grafts, bone, Use of penicillin therapy in conjunction with free, in infected areas, 101; heterogeneous fascial, Fate of preserved, of fascia when transplanted into living human tissues, 145; skin, Severe burns, clinical findings with simplified plan of early treatment, 187;

skin, Surgical aspects of trench foot, 243; bone, Cancellous, for infected bone defects, single stage procedure, 392; skin, Surgical treatment of gangrene in trench foot, 513; Tendon transplantation in hand, 651; cartilage, fat, iliac cancellous bone, Reconstruction of bony defects of face, with special reference to cancellous iliac bone, 761; tube, Combined jaw resection neck dissection for metastatic carcinoma of cervical lymph nodes secondarily involving mandible, 767; tube, Functional restoration of thumb, pollicization of index, 807

Granuloma, Talc, 531

Gynecology, Problem of stress incontinence and its surgical relief, 742

HAND, Anomalous innervation of intrinsic muscles of, 15, One stage tubed abdominal flaps, single pedicle tubes, 205; Tendon transplantation in, 631

Head, injury, Deformations of skull in, studied by "stresscoat" technique, quantitative determinations, 219

Health, Plea for personal case record, ed. 150

Heart, Foreign bodies in, and in relation to, thoracic blood vessels and, I. Techniques for approaching and removing foreign bodies from chambers of, 117

Heel, Structure of calcaneal tendon (of Achilles) in relation to orthopedic surgery, with additional observations on plantaris muscle, 107

Hemostatic agents, Absorbable, ed. 403

Hernia, inguinal, Observations on concept of, repair, 55; abdominal, Technique for repair of postoperative, 200

Histopathologic study, Mandibular tumors, clinical, roentgenographic and, 355

Humerus, Fractures of upper end and shaft of, simple conservative method of treatment, 126

Hypernephroma, Metastatic, of thyroid gland, 493

Hypertension, Operative technique of thoracolumbar sympathectomy, 643

ILIAC bone, Reconstruction of bony defects of face, with special reference to cancellous, 761

Incontinence, stress, Problem of, and its surgical relief, 741

Infections, Protein nutrition of surgical patients, ed. 259; surgical, Use of tyrothridin in, 323; bone, Cancellous bone grafts for infected bone defects, single stage procedure, 392

Injection therapy, Clinical evaluation of sotradecol, sodium alkyl solution, in, of varicose veins, 647

Instruments and apparatus, abduction splint, Fractures of upper end and shaft of humerus, simple conservative method of treatment, 126; for quantitative determinations, Deformations of skull in head injury studied by "stresscoat" technique, 219; rotation splint, Functional restoration of thumb, pollicization of index, 807

Intestines, Malignant lesions of duodenum, 83

Irradiation therapy, Surgery and cancer problem, ed. 129

JAWS, Management of plastic maxillofacial wounds in evacuation hospital, 462; Combined, resection neck dissection for metastatic carcinoma of cervical lymph nodes secondarily involving mandible, 767

KIDNEY, Metastatic hypernephroma of thyroid gland, 493

Knee, Use of penicillin therapy in conjunction with free bone grafting in infected areas, 101

LABOR, Pelvic floor in parturition, 296; Transverse presentation, 473; Management of placenta previa at Chicago Lying-In Hospital, review of 323 cases during 1931 to 1945, 777

Laparotomy, Gastric cancer, resectability, and mortality, 480
 Larynx, Feeding tube stenosis of, 253; Further experiences with panlaryngectomy for advanced carcinoma of, 639
 Leg, Structure of calcaneal tendon (of Achilles) in relation to orthopedic surgery, with additional observations on plantaris muscle, 107; Thrombophlebitis of deep veins in thromboangiitis obliterans, 449
 Lesions, Malignant, of duodenum, 83
 Liposarcoma, of female mammary gland, 216
 Liver, function tests, Experimental study on, 171; Suppurative cholangitis complicating sidetracking operations of biliary tract, 428
 Lobectomy, and pneumonectomy in treatment of pulmonary tuberculosis, ed. 815
 Lungs, Effect of pulmonary resuscitative procedures upon circulation as demonstrated by use of radioactive sodium, 387; Lobectomy and pneumonectomy in treatment of pulmonary tuberculosis, ed. 815
 Lymph nodes, cervical, Combined jaw resection neck dissection for metastatic carcinoma of, secondarily involving mandible, 767

MALARIA, and transfusions, ed. 674
 Mammary gland, See breast
 Mandible, Unusual metastatic manifestations of breast carcinoma, I. Metastasis to, with report of 5 cases, 289; Mandibular tumors, clinical roentgenographic, and histologic study, 355; Combined jaw resection neck dissection for metastatic carcinoma of cervical lymph nodes secondarily involving, 767
 Mastectomy, radical, 205 cases of cancer of breast treated by, 751
 Mastitis, Diagnosis and therapeutics of simple cysts of breast, 239
 Microscopy, polarized light, Talc granuloma, 531
 Micturition, neurophysiologic aspects, Transurethral resection in surgical management of cord bladder, 597
 Mortality, operative, Malignant lesions of duodenum, 83; fetal, maternal, Transverse presentation, 473
 Muscles, of hand, Anomalous innervation of intrinsic, 15; plantaris, Structure of calcaneal tendon (of Achilles) in relation to orthopedic surgery, with additional observations on, 107; gluteus maximus, Exposure of high lesions of sciatic nerve, 369

NECK, Feeding tube stenosis of larynx, 253; wounds, Management of plastic maxillofacial wounds in evacuation hospital, 462; Combined jaw resection, dissection for metastatic carcinoma of cervical lymph nodes secondarily involving mandible, 767
 Nerve, median, ulnar, Anomalous innervation of intrinsic muscles of hand, 15; sciatic, Exposure of high lesions of, 369; vagus, Section of, to stomach in treatment of peptic ulcer, ed. 547; sympathetic, Operative technique of thoracolumbar sympathectomy, 643; periphereal, Causalgia, study of 75 cases, 789
 Nitrofurantoin compounds, Local application of, with special reference to use on wounds, 73
 Nomenclature, Continuity of fasciae lining abdomen, pelvis, and spermatic cord, 575
 Nose, Repair of nasal defects with median forehead flap, primary closure of forehead wound, 37
 Nutrition, in pregnancy, effects of dietary deficiency in pregnancy and detection and treatment of nutritional deficiency diseases, 561

OBSTETRICAL, Pelvic floor in parturition, 296; Outlet pelvimetry, commentary, and presentation of pelvimeter for measuring "symphysis and sacral biparietal

distance," 399; Transverse presentation, 473; Effect of anticoagulants on postpartum bleeding, 528
 Osteomyelitis, Cancellous bone grafts for infected bone defects, single stage procedure, 392; Management of, secondary to war wounds, 507

PANCREAS, Surgical treatment of pancreatic cysts, 181
 Panlaryngectomy, Further experiences with, for advanced carcinoma of larynx, 639
 Parachlorophenol, Local chemotherapy of wounds, tissue toxicity of certain antibacterial substances, 1
 Parturition, See labor
 Penicillin, Local chemotherapy of wounds, tissue toxicity of certain antibacterial substances, 1; Use of, therapy in conjunction with free bone grafting in infected areas, 101; Peritonitis of appendiceal origin treated with massive doses of, report of 50 cases, 150; Identification of Clostridium welchii in mixed cultures and debrided tissue and determination of sensitivity of organism to, 343
 Pelvimetry, Outlet, commentary, and presentation of pelvimeter for measuring "symphysis and sacral biparietal distance," 399
 Pelvis, Pelvic floor in parturition, 296; Outlet pelvimetry, commentary, and presentation of pelvimeter for measuring "symphysis and sacral biparietal distance," 399; Continuity of fasciae lining abdomen, and spermatic cord, 575
 Peritoneum, Primary retroperitoneal tumors, report of 95 cases and review of literature, 705
 Peritonitis, of appendiceal origin treated with massive doses of penicillin, report of 50 cases, 150
 Personal health record, Plea for, ed. 130
 Pilonidal sinus, treatment by primary closure, 64
 Placenta previa, Management of, at Chicago Lying-In Hospital, review of 325 cases during 1931 to 1945, 777
 Pneumonectomy, Lobectomy and, in treatment of pulmonary tuberculosis, ed. 815
 Pollicization, of index, Functional restoration of thumb, 807
 Pregnancy, Nutrition in, effects of dietary deficiency in, and detection and treatment of nutritional deficiency diseases, 561; Management of placenta previa at Chicago Lying-In Hospital, review of 325 cases during 1931 to 1945, 777
 Presentation, Transverse, 473
 Procaine block, Causalgia, study of 75 cases, 789
 Prolapse, uterine, Treatment of, and herniations into vaginal vault by "composite" procedure, 725
 Prostheses, "Heidelberg" forearm, Cineplastic forearm amputations and, 373
 Protein nutrition, of surgical patients, ed. 599
 Pylorus, Congenital hypertrophic pyloric stenosis, ed. 261
RADIATION therapy, Repair of vesicovaginal fistula caused by, 348
 Radioactive sodium, Effect of pulmonary resuscitative procedures upon circulation as demonstrated by use of, 387
 Rectum, Malformation of anus and, 499
 Resection, Transurethral, in surgical management of cord bladder, 597
 Resuscitation, pulmonary, Effect of, procedures upon circulation as demonstrated by use of radioactive sodium, 387
 Roentgen therapy, Therapy for soft tissue sarcomas, experimental study, 653
 Roentgenographic study, Mandibular tumors, clinical, and histopathologic study, 355

SACROCOCCYGEAL fascia, Pilonidal sinus, treatment by primary closure, 94

Sarcoma, Therapy for soft tissue, experimental study, 653

Skull, Deformations of, in head injury studied by "stresscoat" technique, Quantitative determinations, 219

Sotradecol, Clinical evaluation of, sodium alkyl sulfate solution, in injection therapy of varicose veins, 647

Spermatic cord, Torsion of, 163; Continuity of fasciae lining abdomen, pelvis, and, 575

Sphincter of Oddi, Effects of certain drugs on, 210

Spinal fusion, Treatment of painful spondylolisthesis, 797

Spine, Bilateral and multiple ruptured discs as one cause of persistent symptoms following operation, 485; Treatment of painful spondylolisthesis, 797

Splint, finger, Tendon transplantation in hand, 631

Spondylolisthesis, Treatment of painful, 797

Stomach, Gastric digestion of living tissue, 61; Congenital hypertrophic pyloric stenosis, ed. 261; Subtotal esophagectomy with high intrathoracic esophagogastric anastomosis in treatment of extensive cicatricial obliteration of esophagus, 417; Relative surgical curability of certain gross types of gastric carcinoma, 453; Gastric cancer, laparotomy, resectability, and mortality, 480; Section of vagus nerves to, in treatment of peptic ulcer, ed. 547; Gastric carcinoma, incidence and diagnostic procedures, 572; Transthoracic operations for neoplasms of esophagus and, 657; Perforated gastric malignancy, 718; Combined abdominothoracic approach for carcinoma of cardia and lower esophagus, 737

Streptomycin, Local chemotherapy of wounds, tissue toxicity of certain antibacterial substances, 1

"Stresscoat" technique, Deformations of skull in head injury studied by, quantitative determinations, 219

Stricture, benign, Reconstructive operations for, of bile ducts, 24; Benign, of bile duct, ed. 549

Sulfamylon, Local chemotherapy of wounds, tissue toxicity of certain antibacterial substances, 1

Surgery, plastic, Repair of nasal defects with median forehead flap, primary closure of forehead wound, 37; Bassini technique, Observations on concept of inguinal hernia repair, 55; plastic, Pilonidal sinus, treatment by primary closure, 94; orthopedic, Structure of calcaneal tendon (of Achilles) in relation to, with additional observations on plantaris muscle, 107, and cancer problem, ed. 129, plastic, Fate of preserved heterogeneous grafts of fascia when transplanted into living human tissues, 145; Technique for repair of post-operative abdominal hernias, 200, plastic, One stage tubed abdominal flaps, single pedicle tubes, 205; war, Surgical aspects of trench foot, 243, preoperative and postoperative care, Protein nutrition of surgical patients, ed. 259, Fredet-Rammstedt operation, Congenital hypertrophic pyloric stenosis, ed. 261, technique, Chieney incision as applied to surgery of lower ureter and bladder, 364; technique, Exposure of high lesions of sciatic nerve, 369, plastic, Cneplastic forearm amputations and prostheses, 373, hemorrhage, Absorbable hemostatic agents, ed. 403; postoperative complications, Suppurative cholangitis complicating sidetracking operations of biliary tract, 428; plastic, Management of plastic maxillofacial wounds in evacuation hospital, 462, plastic, Tendon transplantation in hand, 631; Therapy for soft tissue sarcomas, experimental study, 653; war, Vascular injuries in, 667; technique, "composite" operation, Treatment of uterine prolapse and herniations into vaginal vault by, 725, technique, Combined abdominothoracic approach for carcinoma of cardia and lower esophagus, 737; plastic, Problem of stress incontinence and its surgical

relief, 742; plastic, Reconstruction of bony defects of face, with special reference to cancellous iliac bone, 761; plastic, Combined jaw resection neck dissection for metastatic carcinoma of cervical lymph nodes secondarily involving mandible, 767; plastic, Functional restoration of thumb, pollicization of index, 807

Sutures, catgut, Study of absorption characteristics of surgical, 521

Sympathectomy, thoracolumbar, Operative technique of, 643

T.A.C., granuloma, 531

Tendon, calcaneal, gastrocnemius, soleus, Structure of, (of Achilles) in relation to orthopedic surgery, with additional observations on plantaris muscle, 107; transplantation in hand, 631

Tests, liver function, Experimental study on, 171; acroclin, Identification of *Clostridium welchii* in mixed cultures and debrided tissue and determination of sensitivity of organism to penicillin, 343

Testicle, Torsion of spermatic cord, 163

Therapy, burn, Severe burns, clinical findings with simplified plan of early treatment, 187

Thiouracil, will not replace thyroidectomy, 249

Thromboangiitis obliterans, Thrombophlebitis of deep veins in, 449

Thrombophlebitis, of deep veins in thromboangiitis obliterans, 449

Thumb, Functional restoration of, pollicization of index, 807

Thyroid, Thiouracil will not replace thyroidectomy, 249; Metastatic hypernephroma of, gland, 493

Thyroidectomy, Thiouracil will not replace, 249

Tissues, living, Gastric digestion of, 61; living human, Fate of preserved heterogeneous grafts of fascia when transplanted into, 145; soft, sarcoma, Therapy for, experimental study, 653

Tissue damage, Talc granuloma, 531

Tissue toxicity, Local chemotherapy of wounds, of certain antibacterial substances, 1

Transfusion, Malaria and, ed. 674

Transthoracic operations, for neoplasms of esophagus and stomach, 657

Trench foot, Surgical aspects of, 243; Surgical treatment of gangrene in, 513

Tube, Feeding, stenosis of larynx, 233

Tuberculosis, pulmonary, Lobectomy and pneumonectomy in treatment of, ed. 815

Tumors, Mandibular, clinical, roentgenographic, and histopathologic study, 355; retroperitoneal, Primary, report of 95 cases and review of literature, 705

Tyrothricin, Local chemotherapy of wounds, tissue toxicity of certain antibacterial substances, 1; Use of, in surgical infections, 323

ULCER, peptic, Section of vagus nerves to stomach in treatment of, ed. 547

Ureter, Chieney incision as applied to surgery of lower ureter and bladder, 364

Urethra, Transurethral resection in surgical management of cord bladder, 597; Problem of stress incontinence and its surgical relief, 742

Urology, Problem of stress incontinence and its surgical relief, 742

Uterus, hernia, prolapse, Treatment of uterine prolapse and herniations into vaginal vault by "composite" procedure, 725

Uterus cervix, Treatment of uterine prolapse and herniations into vaginal vault by "composite" procedure, 725; Management of placenta previa at Chicago

Lying-In Hospital, review of 325 cases during 1931 to 1945, 777

VAGINA, Repair, of vesicovaginal fistula caused by radiation, 348; Treatment of uterine prolapse and herniations into vaginal vault by "composite" procedure, 725; Management of placenta previa at Chicago Lying-In Hospital, review of 325 cases during 1931 to 1945, 777

Varicose veins, Clinical evaluation of sotradecol, sodium alkyl sulfate solution, in injection therapy of, 647

Vasomotor disturbances, Causalgia, study of 75 cases, 789

Veins, Thrombophlebitis of deep, in thromboangiitis obliterans, 449

Vertebra, lumbar, Treatment of painful spondylolisthesis, 797

Vitalium tube, Benign strictures of bile duct, ed. 549

WAR, surgery, Surgical aspects of trench foot, 243; wounds, Management of plastic maxillofacial, in evacuation hospital, 462; wounds, Management of osteomyelitis secondary to, 507; surgery, Surgical treatment of gangrene in trench foot, 513; surgery, Vascular injuries in, 667

Wound healing, Local application of nitrofurazone compounds with special reference to use on wounds, 73; Use of penicillin therapy in conjunction with free bone grafting in infected areas, 101

Wounds, Local chemotherapy of, tissue toxicity of certain antibacterial substances, 1; war, Management of plastic maxillofacial, in an evacuation hospital, 462; war, Management of osteomyelitis secondary to, 507; Causalgia, study of 75 cases, 789

ZEPHIRAN, Local chemotherapy of wounds, tissue toxicity of certain antibacterial substances, 1

COLLECTIVE REVIEW

COLONIC AND PROCTOSCOPIC DISEASES

ROBERT TURELL, M.D., New York

PART II

WAR WOUNDS OF THE COLON

RECENTLY there has been an outpouring of papers dealing with abdominal war wounds which include comprehensive discussions of wounds of the colon.¹ Reference is made to some of the important papers that emphasize basic principles and procedures, and due consideration and emphasis are given to the stimulating but controversial ideas that deviate from the "accepted" ones, which appear in the occasional article.

The main object of this discussion is to correlate what has been learned from the wide experiences gained in the management of casualties of World War II, with a view to the application of this knowledge to the treatment of similar wounds in civilian practice.

Battle Wounds. War wounds of the colon are so closely bound up with those of the other abdominal viscera that they can hardly be discussed separately. The following points are decisive to the success of colonic (and abdominal) surgery performed in the field.

1. Teamwork is necessary to carry out the preoperative, operative, and postoperative care smoothly.

2. Resuscitation is frequently necessary before surgery can be undertaken. In spite of associated shock, immediate surgery is at times performed. When the shock is due to continuing intra-abdom-

Formerly, Major, Medical Corps, United States Army. From the Surgical Service of the Montefiore Hospital, New York, N. Y.
¹This subject has been brought up to-date, the literature of the early part of 1946 being included.

Part I of this review appeared in the November issue.

inal hemorrhage (35, 20), transfusion of blood is most important in the resuscitation program. Great credit is due Richard Lewisohn for his discovery in 1915 of the citrated method of transfusion of blood, which was the greatest lifesaving measure in the management of casualties in the field of battle of World War II.

Ogilvie (35) believes in copious transfusion of blood before, during, and after operation. The effect of blood loss upon the mortality rate of penetrating abdominal wounds may be disastrous. In civilian practice Hamilton observed a mortality of 17.2 per cent when a loss of less than 500 c.c. of blood occurred; the mortality rose to 41.5 per cent when the blood loss ranged between 500 and 1,000 c.c., and it reached 64.6 per cent when more than 1,000 c.c. of blood were lost. This observation was confirmed by Loria of New Orleans. When feasible, autotransfusions may be carried out.

3. Patients with colonic or rectal injuries were usually given the same priority as were patients with other penetrating wounds in the abdomen. In suspected cases a rectal examination is imperative as the presence of blood indicates an injury. When digital examination fails to disclose a perforation, proctoscopy should be performed (32).

4. Ether-oxygen anesthesia by the closed technique is the anesthetic of choice (Also see chapter on anesthesia elsewhere in the text).

5. The incisions should be as simple as possible. The straight median or paramedian incisions that go through all layers of the abdominal wall in the same plane are the best (35). In civilian traumatic practice similar incisions are advocated (15). In

rectal wounds, Laufman prefers a main right paramedian and a left stab iliac colostomy incision. This plan allows more room for occlusive protective dressings. In closure, the peritoneum and the posterior rectus sheath are well approximated while the remaining layers of the abdominal wall are loosely sutured. The skin is best left open. In civil traumatic practice the abdominal wound is drained by placing a cigaret drain to the peritoneum in order to prevent infection or the possible rupture of an abdominal wall abscess into the peritoneal cavity (15). For rapid closure, through and through sutures of steel, silver wire, or heavy silk may be used.

The technique should consist of a simple overhaul and a rapid repair. The forward surgeon "must have good hands, a stout heart, and not too sound philosophy. He is called upon for decision rather than discussion, for action rather than knowledge of what the best writers think should be done" (35). The surgeon at the front should not necessarily do what he thinks will give the best results, but what he knows will avoid the worst danger (36). The source of intraperitoneal hemorrhage must be stopped with dispatch. This source is usually perforation of a large vessel or a tear in the mesentery. The control of mesenteric hemorrhage may be complicated when more than one vessel is damaged and when the tissues are edematous or blood stained. Ogilvie created the dictum "no mass ligatures, no stitches, no catgut." Mass ligature may compromise the blood supply to segments of colon that could have been saved by careful hemostasis, stitches cause more bleeding than they stop, and catgut has a tendency to slip off when the bowel is handled during exploration.

Exteriorization of the colon is regarded by many writers as the greatest single advance in war surgery of the transverse and left colon. This view is not, however, totally shared by some military surgeons (24, 6), nor by Sloan in civil practice. Hamilton and others have advocated the exclusion of even questionably injured segments of the colon because traumatized areas may become devitalized and may slough away some time after exploration. Observation of exteriorized segments of the bowel shows that small perforations of the colon are usually surrounded by an area of ecchymosis which invariably undergoes necrosis and slough (26). The uncertainty of estimation of the extent of the necrosis makes simple closure of colonic lacerations hazardous. Hurt never sutured unprepared colon except for injuries between the sigmoid and the extraperitoneal rectum, supplementing the suture by a proximal colos-

tomy. On the other hand, Blackburn and Rob, and Imes sutured colonic lacerations without fear. Imes has sutured 25 such cases.

Ogilvie (35) believes that injuries of the fixed segments of the colon should be repaired "as well as possible under the circumstances," the retroperitoneal area should be drained adequately through a separate incision, and a proximal colostomy should be performed. However, the American forward surgeons (20, 13) prefer to mobilize the fixed portions of the colon whenever possible by freely incising the lateral peritoneal reflections with a view to facilitating exteriorization.

A large laceration of the mobile portion of the colon may require resection of the involved segment of the bowel and exteriorization of the proximal and distal loops as a double barrelled colostomy. The stoma is preferably brought out through a separate lateral incision in the hypochondriac region without tension in order to avoid infection in the main wound. The wisdom of this maneuver is questioned by Colcock who found an equal incidence of infection (5 per cent) of the wounds in the cases of stab wound colostomy as in those in which colostomy was incorporated in the original laparotomy wound.

When a retroperitoneal hematoma involving the mesocolon is present, the posterior aspect of the colon must be inspected through an incision in the lateral mesenteric leaf (8). If the colon is injured, exteriorization of the bowel becomes mandatory and drainage of the retroperitoneal space through a flank incision is desirable. This policy also applies to the management of solitary colonic wounds when the site of exit is in doubt.

6. *Colostomy.* Colostomies in the left side of the colon are usually performed for (1) colonic injuries when exteriorization is impossible, (2) rectal injuries, and (3) extensive wounds of the perineum and buttocks.

Adequate mobilization of the colon usually permits rapid formation of a long colostomy spur. This in turn facilitates the future restoration of intestinal continuity. Two rows of serosal sutures uniting the limbs of the bowel are desirable and will effectively prevent the omentum or small bowel from getting between the loops of the colostomy spur; when haste is essential one row of sutures will suffice. These sutures approximate the longitudinal bands of the colon and should be tied without tension. Under no circumstances should these sutures pass into the lumen of the colon. In civil practice, Jones (28) maintains the colostomy loops in position by suturing together several epiploic appendages; he never sutures the colon itself, "neither serosa to serosa nor serosa to

any part of the abdominal wall." The colostomy spur should be so constructed that the subsequent application of the enterotome will not crush the blood supply. Any safe surgical "trick" that will save time finds usefulness in military surgery.

Keene (30, 31) believes that neither a double barrelled nor a loop colostomy effectively diverts the fecal stream. Feces will progress from one loop to another if the two stomas are too close together. He believes that the bowel should be completely transected and the two stomas brought out at different sites on the abdominal wall with regard to spur formation. The two intestinal ends should be separated for at least 6 cm. and different dressings applied to each opening.

The closure of colostomies may be done in one of several ways. The classic procedure entails the crushing of the spur and the closure of the anterior wall of the stoma. Before the enterotome is applied it is imperative to make sure that there are no intervening structures between the loops of the bowel, and that the two intestinal limbs are united to each other. This can usually be established by the simultaneous palpation with an index finger in each loop. Following adequate crushing of the spur, the colostomy is converted into a fecal fistula and closure may be effected by a simple extraperitoneal procedure. When the application of the enterotome produces nausea, vomiting, undue pain, especially pain radiating to the back, and urinary tenesmus, the enterotome should be promptly removed and this type of closure abandoned.

Closure of the stoma without crushing of the stoma is a more difficult procedure. Frequently, but not always, an intraperitoneal maneuver is necessary. If the colostomy stoma is very mobile, closure may be performed by the extraperitoneal route. When narrowing at the suture line appears inevitable the stoma may be enlarged longitudinally and sutured transversely. One drain is inserted down to the sutured bowel and the other into the subcutaneous tissues. Recently Sinaiko proposed another simple method of enlarging and closing the stoma.

Keene has employed a one stage intraperitoneal end-to-end anastomosis combined with delayed closure of the wound for all types of interruption of continuity of the large intestine regardless of the anatomic distortion present. This policy was adopted because over 60 per cent of his 40 cases showed "retraction of the bowel ends, loss of colonic substance, wound sepsis, extensive scarring, and the like." Another 10 per cent of the colostomies treated by him had been "rotated through 180 degrees so that the defecating stoma

is situated distal to the other stoma." This, of course, placed the mesentery between the loops of the colostomy stoma. Unsuspected interposition of the small intestines, mesentery, and omentum was found often enough to warrant revision of all types of colonic stomas regardless of the external appearances. In 3 cases of properly performed Mikulicz colostomies Keene found loops of small intestines so placed that an enterotome would have caused considerable injury. As the result of his successful experience with 40 colostomies or fecal fistulas, Keene established the following preoperative, operative, and postoperative program of treatment.

1. Preoperative preparation.

- a. General measures—the patient should be gaining weight.
 - (1). High protein (red meat) diet.
 - (2). Whole blood, red blood cell suspension, and plasma transfusions.
 - (3). Correction of fluid and electrolyte balance.
 - (4). Vitamins.
- b. Evaluation of the bowel and sphincters by roentgenography and sigmoidoscopic examination.
- c. Anterior Bradford frame care if there is digestion or infection of the abdominal wall.
- d. Daily irrigations of both loops.
- e. A low residue diet, and succinylsulfathiazole (to include the distal loop) should be given for 1 week before operation.
- f. For 48 hours preoperatively, sulfadiazine or penicillin should be given in selected cases.

2. Operative technique.

- a. Meticulous irrigation of the colostomy loops with soapy water followed by large amounts of sterile water.
- b. Complete freeing and mobilization of the bowel ends.
- c. Restoration of the anatomic continuity by intraperitoneal end-to-end anastomosis. Two layers of sutures, a through-and-through continuous inverting suture of chromic catgut (size 00), and a serosal layer of interrupted mattress-type No. 60 cotton are used.
- d. Closure of the peritoneum, transversalis fascia, and inner muscle with interrupted chromic catgut (size 1). Silkworm gut sutures are then placed through the skin and outer fascia but not tied. This eliminates serosanguineous discharge and leaves the wound dry.

- e. Wound packed open with one layer of petrolatum gauze plus dry gauze.
3. Postoperative care.
 - a. Wound inspected at 48 hours and, if clean, silkworm gut sutures are pulled and tied.
 - b. Nothing by mouth for 48 hours, then fluids and low residue foods with progressive liberality.
 - c. Intravenous fluids, penicillin, or sodium sulfadiazine continued as indicated.

Routine follow up roentgen studies showed only 1 case of asymptomatic constriction.

7. Simple lacerations of the cecum in the absence of retroperitoneal involvement may be converted into a tube cecostomy with good results. Extensive wounds of the terminal ileum, cecum, and the lower segment of the ascending colon are difficult to manage because of the irritating effect of the intestinal drainage. There is considerable division of opinion as to the proper surgical attack. The iliac stoma is best separated from the colonic stoma by the construction of an ileostomy and the exteriorization of the colon through separate incisions. The anastomosis between the small bowel and the transverse colon should be effected at the earliest practicable moment.

8. *Wounds of Rectum.* Laufman, in an excellent article, stated that contamination of the perirectal space may take place from within and without and described the anatomy of the rectum exceedingly well. The initial operative treatment of penetrating wounds of the rectum, as seen in an evacuation hospital, consisted of (1) complete débridement of the tract, (2) adequate incision of the fascia propria to decompress the perirectal space with suture of the rectal wall when the defect was large, and (3) the construction of temporary proximal colostomy. (Some authors prefer a sigmoid colostomy, while other surgeons, notably Gordon-Watson, prefer a transverse colostomy.) Free posterior drainage was best accomplished by incision of the fascia propria with exposure of the rectal, sacral, and lateral paramedian spaces through a parasacrococcygeal incision without a coccygectomy. Coccygectomy was performed only if concomitant injury to the coccyx was present. If two perforations existed, the incision was placed on the side having the larger laceration, there was no need for an incision on both sides. An attempt was made to close the large rectal wound, especially when it could be found readily. If the defect was small, as visualized by proctoscopy, the rectal laceration was not sutured. Hurt preferred to suture all rectal perforations, while Jarvis and his associates refrained from suturing the rectal wounds because these

usually healed following adequate posterior drainage.

It is highly important to look for concomitant rectal injuries in all entry wounds of the buttocks, the perineum, and the thighs. Such an undetected injury may lead to fatal pelvic cellulitis.

In the event that in the course of a laparotomy there is doubt whether a bullet which entered the buttock or perineum might have gained entry into the true pelvis or the pouch of Douglas, the pelvis should be swabbed with a sponge on a stick as absence of blood on the sponge eliminates the likelihood of perforation (20).

9. Ogilvie (35) observed that "the surgeon who drains most often saves most lives." Estcourt and his collaborators concurred with Ogilvie. They preferred to drain through a stab wound or through the battle wound if it was well placed; they never drained through the main exploratory incision. Blackburn and Rob drained only when the peritoneal cavity was grossly contaminated by feces or bile.

10. Gastric suction is of paramount importance because ileus invariably occurs (35). Nasogastric suction and intravenous therapy with whole blood, protein, plasma, sulfonamides, penicillin, and fluid are continued until equilibrium of the patient is established. A urinary output of 1,500 c.c. is important, especially when sulfonamides are employed. Parenthetically, sulfonamides and penicillin appear about equally effective in the prevention of peritonitis. In general, experience in war surgery has not justified the enthusiasm for chemotherapeutics in the treatment of peritonitis in civilian practice (26).

Intestinal (abdominal, in general) casualties are kept in the forward centers until they have regained equilibrium—an average period of about 10 days. These patients cannot stand travel; even a small move may be fatal. Whenever the military situation necessitated early transport the mortality of these cases invariably rose. Estcourt *et al.* pertinently pointed out that these patients can be moved with fair safety before, but never after, operation.

11. Contamination of the peritoneal cavity (with localized sepsis) and renal insufficiency are two outstanding complications (26). The occurrence of intestinal obstruction or fistulas is quite commonly observed. Individualized appropriate treatment and measures to prevent protein and vitamin depletion should be instituted at an early date.

Rogers called attention to the following danger signs: (1) persistent hiccup starting even during the operation; (2) slow, persistent distention with

a silent abdomen; (3) continual anxiety; (4) tachycardia, and (5) diminution of the urinary output.

Barney and his associates (*Med. Clin. N. America*, 1946, 30:337) reported the frequently encountered mechanical intestinal obstruction following celiotomies for abdominal war wounds. The intestinal obstruction is produced by adhesions. (Also see Garlock's comments elsewhere in the text). In the colon, an inadequate lumen may result following the performance of the Paul-Mikulicz type of colostomy closure.

Underwater Explosion. Cameron, Short, and Wakeley reported their clinical and experimental studies of abdominal injuries due to pressure waves of underwater explosions. The solid abdominal viscera are seldom injured, whereas the gas containing gastrointestinal system is susceptible to grave injuries. The intestinal lesions vary from small intramural hemorrhages to complete tears of the wall. The colon was involved more frequently than the small bowel or the stomach. Experimental studies on goats revealed striking damage to the colon. The lesions consisted of annular hemorrhage in the intestinal wall, perforation of the bowel with prolapse of mucosa, effusion of blood into the lumen, and rectal bleeding.

Gage reported his clinical experiences with 98 men who had survived a sinking at sea and a subsequent depth charge explosion. Practically all the injured men stated that they felt as if they had been kicked in the injured region when the depth charge went off. Twenty-three patients suffered from serious intraperitoneal injury. Practically all of the casualties estimated that they were within 100 feet of the depth charge when it exploded; they were either on their abdomens or they were in water above their abdomens facing the blast. Conservative treatment was instituted because these patients were seen about 36 hours after the explosion. Four of the 23 patients died of generalized peritonitis; these patients were at no time in condition for surgical intervention. Operation instead of nonoperative treatment might have been indicated in some of Gage's patients had they been received within 10 or 12 hours after the injury. Secondary perforation of a viscus occurred in 2 sailors; in one the perforation occurred 40 days after the injury. One patient was promptly operated upon and recovered. Gage believes that nonsurgical treatment is indicated when the optimum period of surgical intervention has passed.

CIVIL TRAUMATIC ABDOMINAL WOUNDS

A number of excellent papers dealing with civilian abdominal injuries have recently been pub-

lished (15, 48, 64). The paper by Dixon, Martin, and Ochsner is reviewed in detail for further emphasis and because the ideas and procedures described therein follow quite closely those associated with war wounds in the forward areas. These authors reviewed 88 personal cases of abdominal injuries encountered in New Orleans. An exploratory laparotomy was performed (1) when shock continued for over an hour in spite of antishock treatment, (2) when lacerated bowel extruded from a torn abdominal wall, (3) when there was an unmistakable rupture of a hollow viscus, (4) when increasing abdominal pain and rigidity was present, and (5) when air under the diaphragm was observed. As in military surgery of forward areas, the paramedian incision is favored. In the absence of free bleeding, exploration is begun at the middle of the transverse colon and is extended toward the right side to the cecum and then toward the left side to the rectum. Then the small bowel is investigated, beginning at the ligament of Treitz to the ileocecal valve. Solitary small intestinal perforations are closed by single pursestring sutures which are reinforced with interrupted fine cotton sutures. For multiple perforations in close proximity, resection with end-to-end anastomosis is carried out. Longitudinal lacerations are closed transversely. Large perforations are closed by means of a Connell stitch and triple zero chromic catgut on an atraumatic needle; this is reinforced by interrupted Lembert cotton sutures. Small lacerations of the colon are treated as has just been outlined; extensive injuries require exteriorization. Systemic sulfonamide chemotherapy is preferred to the intraperitoneal administration. The peritoneum is closed with interrupted cotton sutures.

A detailed discussion of the postoperative care and complications (atelectasis, thrombophlebitis, phlebothrombosis, and localized intra-abdominal infection) is presented.

Traumatic Perforation. Kaufman, Sepico, and Mosig reported 3 cases of traumatic perforation of the rectosigmoid; one was the result of a rectal biopsy, another was caused by a colonic irrigation, and a third by an enema. The intestinal wall was normal in all of these cases. The authors stated that the "foreign literature abounds with reports of rectal injuries due to enema and sigmoidoscopy." A few such reports have emanated from the United States. Alvarez stated that "in my experience I have yet to see a colon which was injured demonstrably by years of enema taking." Kaufman and his associates have reviewed the literature and found that perforation has been caused by the following: (1) sigmoidoscope; (2) enema tips, syringes, nozzles, high colonic

tubes; (3) thermometers; (4) bougies and rectal dilators; (5) electrodes for fulguration of polyps; (6) urethral sounds while making false passages; (7) colpotomy; (8) gunshot wounds; (9) impalement; (10) fracture of the pelvic bones; (11) misguided attempts at abortion; (12) accidents in industries; (13) practical jokes; (14) transurethral operations; (15) hydrostatic pressure; (16) sadism or sexual perversion, and (17) sodomy. All 3 of Kaufman's personal cases were operated upon with 2 survivals. Immediate operative interference is advocated.

Swenson and Harkins reported the sixty-fourth case of perforation (2 complete and 1 incomplete laceration) of the rectosigmoid which was caused by compressed air. They believe that immediate operation is indicated even in suspected cases; the method of repair or suture is, to a great extent, dependent upon the ingenuity of the surgeon. The incomplete lacerations may be sutured longitudinally in the direction of the rupture.

The general consensus favors immediate closure of the perforation because delay of 7 or more hours is invariably fatal (Pearse, H. E.: *Arch. Surg.*, 1941, 42: 850). Occasionally perforations of the rectum or sigmoid which occur during sigmoidoscopic examination may be treated conservatively, especially when a delay of several hours has occurred before the diagnosis was established or in the case of the aged or poor-risk patient (Sallick, A. M.: *Surgery*, 1940, 8: 473).

Rupture of the rectovaginal septum. Wharton reported an unusual case of spontaneous perforation of a rectovaginal septum which was successfully repaired by a simple surgical procedure.

Rectourinary fistula. Wilhelm presented 18 cases of rectovesical or rectourethral fistulas that were caused primarily by surgical trauma and malignant disease. Six cases were seen shortly after perforation had occurred, and in 3 of these the fistulas were cured by such measures as control of hemorrhage and urinary drainage, intestinal bacteriostasis, and induced constipation. Radical reparative surgical procedures were employed in 5 of 9 chronic rectourinary fistulas. Suprapubic cystostomy was instituted in all these cases. Preliminary colostomy was superseded by succinylsulfathiazole chemotherapy. Four fistulas were repaired by the perineal technique of Young, while a modified Young procedure was utilized in 2 other cases. A case of ileorectovesical fistula was repaired through an abdominal approach. Wilhelm believes that rectourinary fistulas caused by trauma or acute inflammatory process will respond to conservative therapy, while those due to a malignant process have a poor outlook.

Foreign Body. Porter reported an interesting case of a Marine who had been attacked and who had "a piece of wood shoved up his rectum." Following this the patient suffered from indefinite abdominal pain, difficulty in urination, and rectal bleeding. Urination was possible only in the sitting, but not in the standing, position. Roentgenography disclosed a straight and perpendicular rectal shadow. Digital rectal examination elicited what appeared to be an "end of a stick 1½ inches inside the rectum." Under spinal anesthesia with the aid of an Ochsner forceps "a stick of wood 10 inches in length and ¾ by 1¼ inches thick was removed. One edge of the stick was irregular, sharp and jagged." Twenty-four hours following the removal of the foreign body the patient voided, and he had a normal bowel movement within 48 hours.

BLEEDING

Stone (50) contributed a very instructive paper dealing with severe bleeding from the rectum which occurs suddenly and produces, at times, varying degrees of shock. It is extremely difficult or impossible to establish the cause of this condition. As a result of his diagnostic efforts, Stone divided these cases into: (1) those in which a definite cause was established; (2) those in which a lesion was discovered that might have been responsible for the bleeding, and (3) those in which no cause could be discovered in spite of intensive investigation. Patients in the third group, mainly those with no detectable lesions, may either bleed intermittently or may never bleed again after the initial episode. Stone listed the following lesions as those which may be suspected or proved as the cause of bleeding: (1) benign tumors, such as polyps and hemangiomas; (2) malignant neoplasms; (3) gastric, duodenal, intestinal, and colonic ulcers including ulcers in Meckel's diverticulum; (4) diverticulosis; (5) regional ileitis and colitis; (6) vascular lesions, such as varicose veins, infarctions, millary aneurysms; (7) trauma from ingested foreign bodies; (8) erosions from pressure of extraintestinal lesions such as aneurysms of the large vessels; (9) blood dyscrasias, and (10) hypertension.

The undiagnosed cases were treated by immediate resuscitative or restorative therapy followed by diagnostic studies; operative interference was avoided as surgery is futile and invites trouble. Operation is indicated for the definitely diagnosed lesions and for those of questionable character if they are believed to be amenable to surgical treatment.

Pfeiffer added to the foregoing list of causes, on the basis of his experience, a small mucous erosion

into an esophageal vein that was discovered at autopsy. Jones (27) reported an interesting case of a resectable reduplication of the small intestine in a girl 5 years of age, which was apparently the cause of the profuse bleeding. Ochsner emphasized cholecystitis and the ingestion of large amounts of acetylsalicylic acid as causes of obscure bleeding from the rectum. The reviewer has encountered rectal bleeding as a result of the administration of 12 gm. of aspirin in divided doses during a period of 24 hours. The bleeding is probably caused by hypoprothrombinemia, which can be relieved by the administration of vitamin K. Christopher stressed hemangioma of the small bowel as a frequently overlooked source of profuse rectal bleeding. Resection of the tumor bearing bowel resulted in complete recovery. Truesdale believes that esophageal hiatus hernia is a frequently overlooked cause of melena. The bleeding is caused by an abrasion or erosion and originates from varices of the cardia or from the base of an ulcer. A rare cause of bleeding from the rectum is carcinoma of the appendix (58).

Baldwin contributed another interesting article on the causes of rectal bleeding. He stressed the fact that hemorrhoids are the most common, and carcinomas the most important causes of rectal bleeding. The lesser known causes of rectal bleeding are arteriosclerosis, uremia and poisoning by arsenic or mercury bichloride. The importance of an accurate history and a proper examination was stressed. Underwood emphasized that rectal bleeding is still frequently inadequately evaluated. Harris stated that a benign bleeding lesion in the anorectum may coexist with a malignant lesion higher up. The importance of this fact should not be underrated because a large number of cases of rectal and colonic malignancies are overlooked when benign lesions, such as hemorrhoids, are found; usually a complete sigmoidoscopic examination is not performed in such cases. Many cases of malignancy in the terminal bowel undergo hemorrhoidectomies because of rectal bleeding. Only continued bleeding from the rectum after hemorrhoidectomy leads to further investigation and to the discovery of the previously overlooked malignant lesion. Garlock, Ginzburg, and Glass stated that about 25 per cent of the patients with cancer of the rectum seen by them had had a hemorrhoidectomy done elsewhere from 2 to 5 months prior to admission to the Mount Sinai Hospital, New York.

DIGITAL EXAMINATION

Stone (51) succinctly stressed the importance of a digital examination combined with sigmoido-

scopy in studying lesions of the lower segment of the digestive tract. Serious disorders, such as carcinoma, which are situated within the reach of the examining finger are overlooked because of the omission of a digital examination. Baldwin stated that from 60 to 65 per cent of all cancers of the colon and rectum occur within the reach of the index finger. There appears to be a reluctance, and even an aversion, on the part of some physicians to insist on a proper digital examination or to train themselves to perform this examination. The late Doctor Brenneman believed that a "rectal examination is an extremely unpleasant experience" and avoided its employment. On the other hand, Peterman voiced his astonishment at the rarity of the performance of a rectal examination in children. Obviously Brenneman's objection and the avoidance of a rectal examination are not shared by all pediatricians. The reviewer's experience with juvenile proctology is not in accord with Brenneman's experience.

In adults, a rectal examination is of distinct help in arriving at the correct diagnosis of appendicitis as it frequently demonstrates tenderness on the right side which results from the inflammatory appendical process in the pelvis (17). Strauss believes that a rectal examination should be made in addition to the examination of the abdomen in all cases of appendicitis.

In the study of intussusception even Brenneman employed digital rectal examination and he stated that in infants suffering from this lesion one should "pay no attention to the painful procedure." Upon withdrawal of the examining digit a turbid currant-jellylike mixture of blood and mucus very often appears, which is pathognomonic of this lesion; occasionally a cervixlike mass with a central dimple may be felt.

Berk, in a study of gastrointestinal problems encountered in the Army, stated that "no single examination is so valuable and informative as is the digital examination of the rectum."

HEMORRHOIDS

There were 2 papers dealing with a surgical departure from the usual anatomic dissection of hemorrhoids (4, 41). Benjamin and his associates free the mucosa from the hemorrhoidal vessels through a small linear incision on the perianal area perpendicular to the anal opening which is about 1.5 cm. from the dentate line. After freeing the hemorrhoids, the hemorrhoidal vessel is morcellated by short bites with scissors. Apparently only ulceration of the mucosa makes such dissection impossible and impracticable because the mucosal continuity cannot be preserved. Rakov

enucleates the hemorrhoidal tumor through a radial incision which begins in the perianal skin close to the hemorrhoidal mass and is carried into the anal canal to the apex of the hemorrhoids. Redundant skin may be removed according to the needs of the individual case. All primary hemorrhoids are thus removed while the secondary ones are dissected submucously through the original incision. Intra-anal packing is avoided because the insertion and the removal of such packing elevates the otherwise flattened cutaneous and mucosal flaps and thus predisposes to "tag" formation. The advantages claimed for this procedure are: (1) the simplicity of technique; (2) the absence of complications and sequelae; (3) diminution of postoperative pain as well as of the period of convalescence, and (4) a better final cosmetic result. This operative procedure is akin to that described by Calman (*Am. J. Surg.*, 1947, 53: 428).

In criticism of the foregoing procedures it may be stated that at least 50 per cent of the patients requiring hemorrhoidectomy have concomitant local lesions which are the result of a local inflammatory process, that also require surgical excision. In fact, the current widely accepted belief is that infection of the anal and perianal tissues, preceded or accompanied by passive congestion, is apparently an important single etiologic factor in hemorrhoid formation. It is the belief of some authorities that inflammation and infection are a common denominator in many anorectal lesions, hemorrhoids included. Hence, the operation of choice for such cases is a nontraumatic procedure that will eliminate not only the hemorrhoidal varices but also the sources and channels of infection, and which will, in addition, provide ample drainage through open wounds in order to promote the restitution of the inflamed and/or infected anal and perianal tissues. The surgical procedures of Milligan-Morgan or Buie have a sound anatomic basis and a perfect underlying surgical principle.

In wartime there was an urgent necessity to save duty hours and therefore to speed up the time of effective healing of anorectal wounds. With this in mind the reviewer deviated from the open nontraumatizing type of hemorrhoidectomy and began to employ the semiclosed and closed types of technique. After a clinical trial with these methods of hemorrhoidectomy in the treatment of large groups of patients he became convinced that the semiclosed type of hemorrhoidectomy, which is very much akin to the procedures of Milligan and Morgan but the subcutaneous structures of the hemorrhoidal bed are approximated

without suture of the skin, is a good procedure in the absence of inflammation or infection of the anorectal tissues. Sulfonamide or antibiotic chemotherapy should be utilized before, and continued after, surgery.

The closed type of hemorrhoidectomy in which all tissues including the skin were closed proved to be an undesirable surgical procedure even when combined with sulfonamides and/or antibiotics, because of the high incidence of complications which far outweighed the advantage of saving duty days.

The electrothermic method of hemorrhoidectomy (Warshaw, Arnheim) was also employed in cases that were deemed suitable for the semiclosed or closed methods of hemorrhoidectomy. It was found to be equally as good as the semiclosed technique and far superior to the closed type of hemorrhoidectomy.

Whitney and Angelo emphasized the value of posterior sphincterotomy in hemorrhoidectomy. Among the many advantages of this procedure are the prevention of postoperative anal sphincter spasm and pain. The reviewer has employed posterior sphincterotomies with satisfaction as a part of hemorrhoidectomy only in those cases in which unexplained preoperative anal sphincter spasm was present. In posterior sphincterotomy the incision is made perpendicular to the fibers of only the subcutaneous component of the external anal sphincter muscle.

PROLAPSE

Smith treated 5 patients with rectal prolapse by a modified procedure of compression amputation. Four of these patients were elderly and frail and had cardiovascular disease, and the fifth was obese. In 4 patients the results were considered good, although postoperative narrowing at the site of amputation was present in 2; the fifth patient had had 2 recurrences. Hayden stated that the experience at the Massachusetts General Hospital indicates that rectal prolapse can be successfully treated by a number of different surgical procedures, and that Smithwick had performed several Delorme operations with considerable success.

The Delorme operation which has been popularized in the United States by Bevan and David is an effective procedure because it not only corrects the prolapse of the bowel, but restores the atonic anal sphincter muscles which have been dilated by the prolapse. The reviewer has modified and simplified the Delorme procedure and has employed it successfully in 5 cases that have been followed up for a long time, and in 2 recent cases.

Under infiltration or low spinal anesthesia with the patient in the inverted or lithotomy position the prolapse is maintained at its full length with the aid of Allis or Babcock forceps. The lithotomy position is employed when a perineorrhaphy is also contemplated at the conclusion of the rectal operative procedure, which requires a complete change of instruments, gowns, gloves, and complete re-draping of the patient. If the patient is placed in the inverted position, a V-shaped incision is first made in the anterior arc of the perianal skin about 1.5 cm. from the anal verge and the dissection is carried cephalad into the anal canal to the apex of the prolapse. Here the incision ends in a V-shaped manner corresponding to the one in the circumanal area and effects an elliptically shaped excision of as wide a strip of mucosa as is deemed necessary. If the lithotomy position is employed the dissection is begun in the posterior aspect. This is done in order to keep the operative field of the opposite side free from blood. The subcutaneous component of the anal sphincter muscle is visualized. At the mucocutaneous junction (pectinate line) the mucosa is thin and friable and requires gentle handling to facilitate the uninterrupted dissection in the proper line of cleavage. The mucosa is usually separated from the muscularis of the prolapsing segment of the bowel by blunt dissection with the aid of curved Mayo scissors; sharp dissection may occasionally be used. Bleeding and oozing may be considerable in amount during the process of separation of the mucosa from the underlying structures and must in all instances be carefully controlled. Perfect hemostasis is essential as elderly patients do not stand loss of blood very well.

Dissections similar to that just described are made in each of the three remaining aspects or quadrants of the circumanal arc of the prolapsed gut. It is important to preserve enough anal skin between these dissections in order to prevent post-operative anal stenosis.

After completion of these dissections, a suture of zero, or finer, chromic catgut is introduced into the denuded area of the muscularis beginning just above the mucocutaneous junction; several bites in successive segments of muscularis are taken until the summit of the prolapse is reached. After these sutures are tied, the formerly prolapsed bowel is pleated or plicated and collapsed in an accordionlike manner; it becomes situated in the pelvis above the puborectalis portion of the levator ani muscle. A small Penrose drain is introduced into the anal canal and removed in 24 hours.

When a perineorrhaphy is performed the levator ani muscles are approximated well in front of the

rectum in order to provide anterior and lateral support to the perineum, anus, and rectum. A procedure akin to perineorrhaphy may be performed in men by making an incision in the perineum as for the classic perineal prostatectomy. The levator ani muscles may be brought together in front of the rectum with ease in order to exert a supportive action.

In summary, this modified operation consists of: (1) segmental excision of the mucosa of the prolapsed bowel; (2) segmental excision of the anal and perianal skin; (3) elimination of the pleating of the external anal sphincter muscle, and (4) the incidental provision of drainage of the rectal wounds to the exterior through the anorectal wounds. Parenthetically, in the presulfonamide era such drainage was regarded as a cardinal necessity in anorectal surgery.

FISTULAS

Jackman discussed the pertinent reasons for failure of operations for anal fistulas. He reviewed the records of 500 patients suffering from anal fistula and found that 43 per cent of these patients had undergone from 1 to 14 unsuccessful operations prior to coming to the Mayo Clinic. Faulty conception of the origin and course of the disease, confusion in regard to the anatomy and terminology, mistaken diagnosis, fear of causing rectal incontinence, inadequate postoperative care, failure to appreciate the danger of performing anorectal operations in the presence of infectious diarrhea, inadequate anesthesia, and lack of teaching facilities in our medical schools are the most frequent causes for failure of the surgical treatment of anal fistulas.

Jackman pointed out that the rules promulgated by John Aderne more than 500 years ago still hold good, namely, that a fistulous tract should be opened from its source to its termination regardless of how much sphincter muscle intervenes. Some surgeons fear to cut through the anal sphincter muscle because of the danger of producing an incontinent anus. The cure of fistulas demands that all tissues overlying fistulous tracts should be incised regardless of the intervening muscle. The chief causes of incontinence are faulty packing or neglect of early treatment of the inflammatory process which irreparably destroys the sphincter muscle. The post-operative care is considered as important as the operation itself.

INCONTINENCE

Ruzic and his associates presented a new method of reconstruction of the sphincter mech-

anism in traumatic or operative anal incontinence. A strong objection may be registered to their use of oil soluble anesthetics as an adjunct to such plastic procedure for Truman has recently shown experimentally that these anesthetic agents tend to delay and prolong the process of healing, to increase the inflammatory reaction, and to produce increased scar formation. Those surgeons employing oil anesthesia in wounds should be aware of the facts and ready to accept an increased inflammatory reaction and delay in healing (56). The reviewer has repeatedly called attention to the objectionable features of the long acting (water or oil soluble) anesthetics when applied to wounds (*Am. J. M. Sc.*, 1941, 202: 282, *Surg. Gyn. Obst.* [Internat. Abstr. Surg., 1943, 76: 193]). There are many competent proctologists who believe that when clean cut surgery plus preoperative and postoperative care are employed there is no need for the long acting anesthetics; at best these agents are poor substitutes for good surgery. Ferguson believes "that their disadvantages seem to outweigh their advantages."

Blaisdell, several years ago, contributed a constructive series of papers dealing with the problem of incontinence. The surgical principles then enunciated have been recapitulated in a recent article. The reader is referred to the original papers and to one of my past reviews (*Am. J. M. Sc.*, 1941, 202: 282).

PLASTIC PROCEDURE FOR PRURITUS ANI

Young and Scott have proposed a plastic two stage surgical procedure for intractable anal pruritus. The operation is performed by excising one-half of the perianal skin at one time in order to avoid possible postoperative infection with subsequent prolonged healing and scarring which in turn may result in contracture of the anal aperture. Following excision of the involved skin on one-half of the circumanal area a flap of healthy skin from the medial surface of the buttock and thigh is immediately shifted to the excised area. The technique is as follows:

"An incision is made at the mucocutaneous junction around one-half the circumference of the anus. The mucosal edge is prevented from retracting inward by a number of guy sutures which are held by an assistant. The external sphincter muscle is exposed and the scarred skin and subcutaneous tissues are dissected from it. A plane of dissection is found under the leathery area and the dissection is carried outward from the normal skin. The flap of scarred tissue is then cut away. A flap of skin and subcutaneous tissue of correct

size and shape to cover the defect is cut lateral to the defect with its base posteriorly. It is swung across and sutured to the anal mucosa and to the medial lines of excision. The defect left laterally is sutured as far as possible. If tension is observed, the remainder of the defect is left to granulate. A small rubber drain is brought out from under the flap at its base and a snug perianal binder is applied to hold the flap securely in apposition to its bed. The bowel is prevented from moving for 10 to 14 days depending upon the speed of healing. Infection is moderate. There is usually some inflammatory reaction along the suture line but not enough to interfere with healing. In 2 to 3 months the remaining half of the perianal skin is removed and sutured in the same manner."

Two of the authors' 3 patients have been symptom free long enough to be regarded as permanently relieved; the third patient was still undergoing treatment at the time of writing of the present article. This operative procedure is a welcome addition to the therapeutic armamentarium of intractable anal pruritus especially in view of its apparent simplicity and easy execution. The reviewer treats intractable pruritus ani by tattooing the involved cutaneous area with mercury sulfide. Most patients who show characteristic cutaneous changes that are associated with pruritus of long standing but without associated anorectal lesions have responded well to tattooing (*J. Invest. Dermat.*, 1940, 3: 289; *Am. J. Obst.*, 1941, 42: 299; *Ann. Surg.*, 1942, 115: 126; and *New York State J. M.*, 1942, 42: 1335).

CONDYLOMATA ACUMINATA

Culp and Kaplan reported on the successful treatment of 200 cases of condylomata acuminata occurring at various anatomic sites, including the anal and perianal regions, with podophyllin as a 25 per cent suspension in mineral oil. Ross has employed this drug in the powder form with equally successful results. Most lesions disappeared within 4 days after a single application of podophyllin. No ulceration or scarring followed this therapy. Recurrence or new condylomata may occur since this form of therapy does not remove the primary cause. Podophyllin may also be used in granuloma inguinale and for the destruction of excessive granulation tissues in surgical wounds; for the latter it is superior to silver nitrate. Podophyllin is of no value for the eradication of horny verrucae, condylomata lata of syphilis, or benign intestinal polyps.

Anderson (*Arch. Dermat. & Syph.* 1946, 54: 66) employs a 10 per cent tincture of resin of podophyllum. Sullivan (personal communication) uti-

lizes a 20 per cent podophyllin in 95 per cent alcohol. These solutions may be applied to the lesion with a cotton swab or camel's hair brush.

CRAMP IN RECTUM

Pruitt recently described the clinical characteristics of 23 patients suffering from cramp in the rectum. The pain occurred most often at night during sleep and was "intense, spasmodic and tonic in type, of short duration and localized by the patient as 'in the rectum.' The pain was unaffected by the act of defecation and disappeared spontaneously without sequelae. The cause is obscure and relief of pain is usually spontaneous." Rosser believes that the condition described by Pruitt is produced by an intussusception of the sigmoid into the rectum which occurs during sleep and is frequently relieved by activity. Andrews described a similar condition which was produced by a neuroma of the spinal cord which was removed surgically with complete relief. Brashear recorded 1 instance of nocturnal rectal cramp in a man who was relieved by transurethral resection of the prostate, and another case in a woman who experienced complete relief following a pelvic operation. Thiele believes that the syndrome described by Pruitt represents acute spasm of the levator ani muscles. Thiele, as a result of his continued studies, thinks that spasm of the levator muscles is due either to injury of the coccyx or to chronic infection in the adjacent organs such as anal structures, posterior urethra, prostate, cervix, or vagina. Massage of the levator ani muscles plus the elimination of the local foci of infection (cryptitis, prostatitis, endocervicitis) is the effective treatment.

While on the subject of foci of infection it is not amiss to note that authorities agree that it is unwise to allow a focus of infection to remain if it can be eradicated without detriment to the host. The removal of anorectal focal infection is technically easy and does not entail the sacrifice of vital structures.

BACKACHE IN GASTROINTESTINAL DISEASE

Rivers and Roodenburg have presented an important and enlightening article dealing with the mechanics and pathways of back pain in disease of the gastrointestinal and accessory gastrointestinal (gall bladder and pancreas) tracts. In diverticulitis of the colon when localizing pain over the abdomen develops there may be some back pain which coincides with the location of the abdominal pain. With the formation of diverticular abscess associated back pain is the rule. "Usually this can be utilized in arriving at an accurate lo-

calization of the lesion because it corresponds quite definitely in segmental distribution to the intra-abdominal spinal nerves involved by the spread of the infectious process." In ulcerative colitis with deep involvement of the colonic wall, back pain is present. Only when the lesion is extensive and has penetrating characteristics is the back pain noticed, otherwise it is not recorded by the patient except on direct questioning as pain is overshadowed and obscured by other manifestations of the disease.

In carcinoma of the colon and rectum back pain usually signifies a penetrating type of lesion; hence, its diagnostic and prognostic importance. Cancer of the rectum may produce pain in the sacral area whereas a carcinoma of the sigmoid colon frequently is productive of pain in the lumbar region. Occasionally back pain is the only complaint. Cancer of the other segments of the colon seldom produces pain except when fixation to an adjacent organ takes place during the progression of the erosion of the disease. Then there may occur severe localizing back pain which is usually ipsilateral to the portion of the organ involved. The authors believe that unilateral shifts of pain are due to penetrating lesions usually along the cord along the branches of the spinal column; in these cases the pain is boring, localized, bilaterally felt, and constant. In connection, attention should be called to the anatomic studies of the vertebral system (Batson) through which the spread of metastases in intraperitoneal organs to the vertebral system can take place (33). This has been discussed elsewhere in the text.

PART III

IMPORTANT ALLIED SUBJECTS

THE important recent advances in the fields of biochemistry and physiology alone have greatly affected the practice of surgery, of which coloproctology is an important branch. The early recognition of pathological processes and the ability to treat disease properly are greatly influenced by a wide knowledge of basic physiological processes. The modern surgeon is to a degree an anatomist, surgical pathologist, and a physiologist. In surgery and its specialties, one must keep abreast of progress in all biological sciences in order to be in a position to take better care of the patient. It is with these principles in mind that most of the following subjects have been incorporated in this review.

Metabolic studies. Collier and his associates (11) have shown that there is a high incidence of salt intolerance following general anesthesia. Therefore they recommended that saline solutions be withheld the day of operation and during the first 2 days after surgical intervention, and that dextrose solutions in distilled water be used to satisfy the fluid requirements.

Great care should be exercised especially in administering isotonic saline or Ringer's solution to patients who are hypoproteinemic, anemic, acidotic, or oliguric.

Ireneus is in complete agreement with the work of Collier and his collaborators, and called attention to the infrequent hypochloremic state that many develop postoperatively. The hypochloremic state is a rare clinical entity and is equivalent to heat exhaustion. The advanced symptoms of this condition simulate those of surgical shock and extreme prostration. The clinical picture of the hypochloremic state is difficult to differentiate from salt intoxication, the acute abdomen, postoperative ileus, and intestinal obstruction due to nutritional edema; only the estimation of the blood chlorides clinches the diagnosis. Active treatment is obvious—the administration of massive doses of fluid and salt plus cortical adrenal extract as an aid to the retention of salt in the tissues (Soffer *et al.*, 1944). Prophylaxis consists of frequent determinations of the blood chlorides in suspected cases and the use of saline solution when indicated.

Continuous spinal anesthesia. Numerous comprehensive articles dealing with the continuous or fractional method of spinal anesthesia (Lemmon) have appeared in the recent literature. A continuous drop method of inducing and maintaining spinal anesthesia has recently been proposed and is now on trial (Arrowood and Foldes). With continuous spinal anesthesia it is possible to obtain

literature and his own observations Leithauser concluded that early rising should be instituted during the first 24 postoperative hours when the vital capacity is at a low level; immediately after recovery from the anesthetic is the best time.

There occurred no ematation in the 900 of his personal cases. "The tensile strength of sutures is greater during the early postoperative period and healing is promoted through ambulatory activity." Early rising relieves postoperative distress, promotes rapid recovery, and returns the patient to work early. These aspects have special value in military practice. "The chief obstacle to early rising is fear and respect for tradition on the part of the surgeon and patient."

Nelson critically analyzed a series of 429 operations performed through 426 incisions of the anterior abdominal wall after which early ambulation was instituted. The majority of his patients walked the day of the operation or within the first 24 hours. Nelson is in substantial agreement with Leithauser's studies and conclusions. Nelson believes that early postoperative ambulation is a sound advance in surgery and recommends its universal adoption.

Andrus and Barnes listed the following as contraindications to early ambulation: (1) cardiac failure, (2) shock, (3) severe anemia, (4) cachexia, (5) hemorrhage, (6) the possible presence of thrombi and emboli, (7) peritonitis, (8) cholangitis, (9) pancreatitis, (10) liver infections, (11) potentially infected wounds, (12) copious tamponade, and (13) prolonged preoperative rest.

Intravenous clotting. In recent years clinicians, primarily surgeons, have recognized the frequency of intravenous clotting originating in the deep veins of the legs as an all too frequent source of fatal and nonfatal pulmonary embolism. These "recent" facts have, however, been known to pathologists for a long time. Castleman, on the basis of autopsy investigation, asserted that in about 95 per cent of the cases seen at the Massachusetts General Hospital the source of pulmonary embolus resided in the deep veins of the legs. McCartney studied the records of 25,771 autopsies and found that 4,070 of the deaths followed operative procedures. In his postoperative material there were 471 cases, 11.5 per cent, in which thromboembolism was present, and 216 patients, 5.3 per cent, who had apparently died as a result of pulmonary embolism. Further analysis of the autopsy material showed that thrombosis or embolism followed surgery performed upon certain parts of the body. Fatal embolism following colonic surgical procedures occurred in 5.4 per cent of the cases; these operations took fifth place among the

operations which might lead to fatal embolism and seventh place among those which were actually followed by fatal embolism. Appendical operations took fourth place with regard to the number of fatal embolisms which occurred. McCartney's figures also showed that the incidence of venous thrombosis, with or without pulmonary embolism, and of fatal pulmonary embolism increased with age. In colonic operations there were no fatalities from embolism before the fifth decade of life, although the peak of the incidence of thromboembolism occurred in the seventh decade of life.

In thrombophlebitis, clotting results from injury to the vascular endothelium produced by mechanical or chemical trauma or by bacterial invasion. The clot is firmly attached to the vein and does not easily become detached as an embolus. Embolism may occur when a loosely adherent red or coagulation thrombus forms proximal to the fixed or firmly attached white thrombus. In phlebothrombosis, on the other hand, the clot is the result of alterations in the clotting tendency of the blood and venous stasis, hence is unassociated with inflammation of the vein wall. The thrombus is loosely adherent to the vein wall and may easily be detached and produce an embolus.

In recapitulation it may be stated that the general causes of thrombosis are: (1) slowing of the blood stream; (2) changes in the composition of the blood, and (3) trauma which may include a surgical procedure. Slowing of the blood flow has been considered as a very important causative factor. Changes in the composition of blood include alterations in the prothrombin time, clotting time, calcium value, sedimentation rate, platelet count, infection, and so forth. Wright has shown that the platelets begin to rise on the fourth day following a surgical operation and are most numerous on the twelfth postoperative day, and they fall back to normal on the twenty-first postoperative day. These phenomena apparently correspond with the clinical onset of postoperative thrombosis, although, according to Newburger, postoperative thrombosis may begin before the third postoperative day. Homans (23) believes that "life in bed, the reclining position, abdominal distention, enfeeblement of the circulation and elevation of venous pressure in the lower limbs, perhaps combined with muscular relaxation and atrophy of the legs" are the dominant etiologic factors. Hunter and his associates believe that the "common denominator in phlebothrombosis and pulmonary embolism is confinement to bed. The reason for going to bed is un-

experimental and clinical studies of intestinal motility and postoperative distention. He noted that the action of the small and large bowels was contrary; when the colon is motile the small intestine is quiet, and vice versa. Opiates, prostigmine, physostigmine, and acetylcholine derivatives stimulate the small, but inhibit the large bowel. Posterior pituitary extract and pitressin inhibit the small, but stimulate the large bowel.

Postoperative ambulation. The most provocative discussion on the use and abuse of bed rest was initiated by Dock. This discussion was aimed to undermine the present day ill conceived but well established foundations of bed rest as a therapeutic measure. It was shown that lying in bed is sometimes an inferior means of securing absolute rest than sitting quietly in a chair, because many patients are more restless in bed than they are in a chair. Studies of basal metabolic rates have shown that the energy exchange while sitting in a chair is not materially higher than that of a patient lying in bed. Lying in bed leads to impairment of the appetite, distention, constipation, prostatism with or without retention of urine, bed sores, loss of muscle tone with atrophy, loss of calcium from the skeleton with calcinuria and the formation of renal lithiasis, and also to depression of the morale. The use of the commode entails less discomfort and danger than does the use of a bed pan. Pulmonary embolism (which is discussed fully elsewhere in the text) is perhaps the most serious consequence of bed rest. Postmortem studies at the New York Hospital revealed that more people die from massive pulmonary embolism which is a direct result of complete bed rest than from many serious illnesses and from all the drugs combined.

It should be pointed out that until the era of Florence Nightingale the sick usually got up several times daily for elimination, and perhaps also for meals. The development of the profession of nursing has ushered in the era of complete bed rest with absolute quiet which is aided by the extensive administration of hypnotics and narcotics. As a result, the patient lies flat in bed and is guarded against moving by the solicitous nurse as well as by the medication. "As with all perversions from biologic normality, this too must be paid for by discomfort, invalidism, and death."

Early ambulation following intra-abdominal operations was first proposed by Ries in 1899, but this practice did not find acceptance until recently. The term early ambulation needs precise definition as some surgeons ambulate their patients on the day of the operation or on the first postoperative day, while other surgeons allow their

patients out of bed on the third or fourth postoperative days.

Leithauser stated that "as a result of getting patients out of bed on the first postoperative day and increasing their activity as tolerated, circulatory and pulmonary complications have been reduced to a minimum, intestinal function has been restored without enemas, and the period of morbidity and disability has been diminished 50 per cent or more." Leithauser reviewed 29 foreign articles comprising aggregate studies of over 15,000 patients who had been subjected to early ambulation and found only 3 definite instances of fatal emboli in this group of patients. He also reported his personal experience with 900 private patients.

Leithauser presented evidence gathered from published reports which showed that reflexes from the incision and traumatized areas have a definite relationship to the development of many avoidable complications. Immediately after an abdominal surgical procedure, as a result of reflex to the diaphragm, there occurs a diminution in vital capacity which gradually improves following the first postoperative day and becomes normal between the seventh and fourteenth postoperative days. "The extent and duration of the reduction in vital capacity bear a direct relation to the extent of the surgical procedure." Numerous investigators have "emphasized that pulmonary complications increase in direct proportion to the reduction and duration of reduction of vital capacity." About 90 per cent of primary postoperative pulmonary complications arise before the end of the fourth day while 50 per cent of these are established within 24 hours. Reflex phenomena also exert an effect on the vascular bed and the functional activity of the vital organs. Pathological reflexes to the vital organs (kidneys, liver, and so forth) and the vascular bed occur immediately after the abdominal incision is made and promote anoxia, incomplete metabolism, and faulty elimination. The intensity and the prolongation of these pathological reflexes increase the morbidity and complications. Early ambulation, deep breathing, and coughing exercises stimulate the circulation and respiration and hasten recovery by decreasing the deleterious reactions arising from the abnormal reflexes. Coughing exercises expel mucous plugs from the bronchial tree and are very beneficial in the presence of pulmonary complications. In the standing position the weight of the intra-abdominal organs lowers the diaphragm and thus facilitates the return of vital capacity to normal by allowing air to enter beyond the mucous plugs. From a study of the

literature and his own observations Leithauser concluded that early rising should be instituted during the first 24 postoperative hours when the vital capacity is at a low level; immediately after recovery from the anesthetic is the best time.

There occurred no eventration in the 900 of his personal cases. "The tensile strength of sutures is greater during the early postoperative period and healing is promoted through ambulatory activity." Early rising relieves postoperative distress, promotes rapid recovery, and returns the patient to work early. These aspects have special value in military practice. "The chief obstacle to early rising is fear and respect for tradition on the part of the surgeon and patient."

Nelson critically analyzed a series of 429 operations performed through 426 incisions of the anterior abdominal wall after which early ambulation was instituted. The majority of his patients walked the day of the operation or within the first 24 hours. Nelson is in substantial agreement with Leithauser's studies and conclusions. Nelson believes that early postoperative ambulation is a sound advance in surgery and recommends its universal adoption.

Andrus and Barnes listed the following as contraindications to early ambulation: (1) cardiac failure, (2) shock, (3) severe anemia, (4) cachexia, (5) hemorrhage, (6) the possible presence of thrombi and emboli, (7) peritonitis, (8) cholangitis, (9) pancreatitis, (10) liver infections, (11) potentially infected wounds, (12) copious tamponade, and (13) prolonged preoperative rest.

Intravenous clotting. In recent years clinicians, primarily surgeons, have recognized the frequency of intravenous clotting originating in the deep veins of the legs as an all too frequent source of fatal and nonfatal pulmonary embolism. These "recent" facts have, however, been known to pathologists for a long time. Castleman, on the basis of autopsy investigation, asserted that in about 95 per cent of the cases seen at the Massachusetts General Hospital the source of pulmonary embolus resided in the deep veins of the legs. McCartney studied the records of 25,771 autopsies and found that 4,070 of the deaths followed operative procedures. In his postoperative material there were 471 cases, 11.5 per cent, in which thromboembolism was present, and 216 patients, 5.3 per cent, who had apparently died as a result of pulmonary embolism. Further analysis of the autopsy material showed that thrombosis or embolism followed surgery performed upon certain parts of the body. Fatal embolism following colonic surgical procedures occurred in 5.4 per cent of the cases; these operations took fifth place among the

operations which might lead to fatal embolism and seventh place among those which were actually followed by fatal embolism. Appendical operations took fourth place with regard to the number of fatal embolisms which occurred. McCartney's figures also showed that the incidence of venous thrombosis, with or without pulmonary embolism, and of fatal pulmonary embolism increased with age. In colonic operations there were no fatalities from embolism before the fifth decade of life, although the peak of the incidence of thromboembolism occurred in the seventh decade of life.

In thrombophlebitis, clotting results from injury to the vascular endothelium produced by mechanical or chemical trauma or by bacterial invasion. The clot is firmly attached to the vein and does not easily become detached as an embolus. Embolism may occur when a loosely adherent red or coagulation thrombus forms proximal to the fixed or firmly attached white thrombus. In phlebothrombosis, on the other hand, the clot is the result of alterations in the clotting tendency of the blood and venous stasis, hence is unassociated with inflammation of the vein wall. The thrombus is loosely adherent to the vein wall and may easily be detached and produce an embolus.

In recapitulation it may be stated that the general causes of thrombosis are: (1) slowing of the blood stream; (2) changes in the composition of the blood, and (3) trauma which may include a surgical procedure. Slowing of the blood flow has been considered as a very important causative factor. Changes in the composition of blood include alterations in the prothrombin time, clotting time, calcium value, sedimentation rate, platelet count, infection, and so forth. Wright has shown that the platelets begin to rise on the fourth day following a surgical operation and are most numerous on the twelfth postoperative day, and they fall back to normal on the twenty-first postoperative day. These phenomena apparently correspond with the clinical onset of postoperative thrombosis, although, according to Newburger, postoperative thrombosis may begin before the third postoperative day. Homans (23) believes that "life in bed, the reclining position, abdominal distention, enfeeblement of the circulation and elevation of venous pressure in the lower limbs, perhaps combined with muscular relaxation and atrophy of the legs" are the dominant etiologic factors. Hunter and his associates believe that the "common denominator in phlebothrombosis and pulmonary embolism is confinement to bed. The reason for going to bed is un-

erly patients requiring major abdominal surgery for cancer. They believe that the "interruption of a normal femoral vein is harmless."

Chemotherapy with heparin and dicumarol is on trial at the present time. These drugs, given alone or simultaneously, appear to be indicated for patients with a history of antecedent venous thrombosis or embolism. However, Fine and Starr believe that heparin and dicumarol are not dependable drugs for the prophylaxis of pulmonary embolism. De Bakey cautions editorially that these anticoagulant drugs may cause postoperative hemorrhage. Barker and his associates admit that dicumarol carries a "small risk of bleeding." Work is now in progress in Boston which deals with the beneficial effects of dicumarol employed postoperatively (1). The results are expected to be published soon.

Poor risk patients. Andrus and Barnes contributed an instructive article dealing with surgery in the poor risk patient. They discussed the cardiac, gastrointestinal, respiratory, hepatic, and metabolic aspects of this problem. They also discussed the newer knowledge concerning the administration of fluids, electrolytes, plasma protein, and vitamins. When vitamins are indicated in surgical patients, adequate preoperative and postoperative dosages (thiamine, 50 mgm.; riboflavin, 10 mgm.; niacin, 100 mgm.; ascorbic acid, from 500 to 1,000 mgm.; and vitamin K, 2 mgm.) should be administered.

It may here be interpolated that hypoproteinemia in surgery has received extensive studies in recent years. When a high protein diet cannot be ingested in hypoproteinemia, it is imperative to deliver an adequate protein supply to surgical patients by the parenteral administration of pure amino acids, casein hydrolysate, blood, plasma, or ascitic fluid.

PSYCHOSOMATIC MANIFESTATIONS

Menninger stated that the medical officer, more than the civilian doctor, is "faced with personality deviations expressed sometimes in behavior, sometimes in physical functional complaints, sometimes in frank psychiatric syndrome." He succinctly discussed the relative importance of psychiatric factors in 5 general groups of illness and the attitude of the medical officers toward these psychiatric factors. A medical officer who is ignorant of the patient's emotional factors handicaps his own efficiency and the patient's health. To a degree treatment will vary, depending on the medical officer's personal status; some develop a vindictiveness toward the soldier which they would never display in civilian life. It is not un-

common to hear a medical officer say "the bastard isn't going to get away with this" or "if I can't get away with it, by the gods, neither will you." General Menninger, in a spirit of constructive criticism, pointed out the errors observed in the medical and surgical wards and the ways and means to their elimination. It is important to learn to know and to appreciate the patient as well as his complaint and disease. The patient may not know the cause of his trouble but he knows how he feels, whereas the physician may know the cause but he does not know how the patient feels. The patient usually senses whether his physician is interested or is going through the motions. General Menninger's article should be read and reread by everyone interested in the psychosomatic aspect of medicine and surgery.

Shacter stated that psychosomatic symptoms of patients who consult the surgeon must neither be overlooked nor ignored. They are the expression of emotional disturbances manifested as organic complaints through the autonomic nervous system. Psychogenic symptoms may resemble those produced by organic and operable lesions. Patients who have a multiplicity of complaints and an operable lesion that is not responsible for all of their complaints should, for obvious reasons, be told of the nature of their complaints before surgical therapy is instituted.

Rosenblum discussed pruritus vulvae in which the psychogenesis of the disorder was that of hysterical conversion symptom. Becker believes that 90 per cent of pruritus vulvae or ani is functional in nature and that the remaining 10 per cent has an organic basis. He observed overactivity and oversensitivity in these patients. "Overactivity results in the formation of products of exhaustion. Oversensitivity results in exaggerated emotional reactions which increase the exhaustion." Rothman stated that thickening of the epithelium occurs as a result of chronic scratching and this epithelial change increases the susceptibility to pruritic stimuli, hence, the justification of local therapy for psychogenic vulval or anal pruritus. Thickening of the epithelium not only diminishes the threshold to physiological pruritic stimuli but it also causes inadequate stimuli, such as cold and the finest touch, to elicit a paroxysm of pruritus. Therefore, localized pruritus is regarded as both a psychic and a somatic problem.

Daniels stressed the importance of personality factors in the precipitation and recurrence of ulcerative colitis which is a recurrent, wasting, and, frequently, a fatal disease without an established etiology. In the majority, but not in all cases, the emotional factors are important and the gross

is separated from the sacrococcygeal fascia and removed. A lateral incision through the gluteal fascia in the line of the original incision is now made on either side. It is deepened into the fibers of the gluteus maximus and the fibromuscular flap thus created is turned medially and sutured to its fellow of the opposite side, in the midline. This fills in the area dorsal to the sacrum, eliminates the dead space, and furnishes an abundant blood supply to the base of the wound. The lateral flap slides medially over the edge of the sacrum and is sutured to the opposite lateral flap without tension. The skin is now easily approximated."

It is important to secure perfect hemostasis and to approximate the caudal end of the wound accurately. This operative procedure is especially applicable for primary closure of large uninfected pilonidal cysts or of those infected cysts that have been thoroughly drained prior to operation. The reviewer has successfully employed this operation with a slight modification, namely, the principle of delayed closure of the wound is utilized (51).

Small or medium sized pilonidal cysts can be eradicated and closed primarily without tension by simpler techniques, such as that employed by Gage. The application of the sponges over the wound to help obliterate the dead spaces is a good additional aid to all techniques of primary closure.

In military hospitals various primary closure techniques have been employed with variable success. This is evidenced by published reports and civilian testimony of competent observers like Frank H. Lahey.

Enucleation excision of the pilonidal cyst and sinus and primary closure with drainage as contrasted to excision en bloc is advocated by Bartlett. An oblique incision of the skin is made and the fat is closed from side to side as well as to the fascia in order to obliterate dead space. A small soft rubber drain is placed to the depth of the wound, which is usually removed on the first day of the operation. Bartlett believes that only "a wound of this region in which hemostasis is literally perfect should be left undrained." Valid objections may be raised to the use of a drain as a persistent draining sinus may result in some cases, as occasionally occurs following the Morter procedure.

Worthwhile partial closure techniques are those described by MacFee and Mutschmann and Mitchell. In these procedures the lesion is excised en bloc and the skin edges are sutured, without tension, to the sacrococcygeal fascia in the midline, an open area, from 0.2 to 0.5 cm. in width, being left between the skin edges for granulation and epithelialization. However, Bartlett has ob-

served instances of poor healing after this type of operation, that was associated with pain upon sitting and required secondary surgical treatment.

Recently, Brockbank and Floyd have reported favorably on the so-called marsupialization or saucerization operation which was first described by Buie a long time ago and was again discussed by him in a recent communication. In this procedure the roof and most of the sides of the cyst are removed but the floor which overlies the fascia is undisturbed. The skin edges of the wound are sutured to the edges of the cyst. The remaining cyst wall is said to undergo squamous metaplasia. Bartlett, on theoretical grounds not substantiated by his personal experience, questions the validity of the evidence for the claim that the remaining cyst wall will assume the characteristics of skin.

Immediate skin grafting following excision of the cyst and sinus bearing tissues apparently first performed by Scarborough, has been advocated by Weeks and Young. Intermediate or thick split thickness grafts are used. It should be pointed out that while this is an excellent surgical method it does not save duty hours because the grafted skin cannot usually withstand the strain incident to full military physical duty.

The choice of form of anesthesia employed in the surgery of pilonidal disease is of importance. Brockbank and Floyd are opposed to local infiltration anesthesia because it increases the incidence of complications and recurrences as well as the period of hospitalization. Forty-seven patients who had been operated upon under spinal anesthesia were hospitalized for 21.1 days after operation, while 116 patients who were operated upon under local anesthesia remained in the hospital for a period of 46.8 days. There were 6 severe infections following local anesthesia and none following spinal anesthesia.

The value of chemotherapy in pilonidal disease is discussed in the chapter dealing with chemotherapy.

SURGERY OF THE HEAD AND NECK

HEAD

Stralch, C. L., and McEvitt, W. G.: Total Avulsion of the Scalp. A Review of the Problem with Presentation of a Case of Skin Graft in Which Thrombin Plasma Fixation Was Used. *Occup. M.*, 1946, 1: 451.

Traditionally a woman's hair is her crowning glory. To suffer the irremediable loss of complete scalping is one of the most terrible of afflictions. A malignant fate seems to increase the disaster by visiting the misfortune on young women to whom physical attractiveness is a pearl beyond price.

While not rare, this accident is sufficiently uncommon that many experienced surgeons have never dealt with the condition. The treatment is that of a real emergency, and there is then no time for study. Therefore, it is not surprising that even recent case reports show the same errors that have been made by surgeons for a century. Few physicians have the opportunity to attend a second case.

Total avulsion involves complete separation of the entire scalp from the cranium.

Today complete scalping, as one would expect, is confined almost entirely to women. The scalp is usually considered to have five layers—skin, subcutaneous tissue, the aponeurotic layer, the subaponeurotic layer, areolar tissue—and the periosteum. The subaponeurotic layer is loosely woven.

The authors have included the history of scalping and the anatomy of the scalp as well as the mechanism of total avulsion of the scalp. The symptoms, physical signs, and subsequent course of the untreated injury are outlined.

The mechanism of total avulsion is by pull in an oblique direction. Rarely is any of the face below the eyes, or the neck below the hairline, affected. The scalp should be saved and may be utilized. It is extremely important also that the hair be rescued and preserved, as it makes the best possible kind of wig.

A case of complete avulsion is presented in which a successful graft was made at 1 major operation and 2 minor ones. A thick dermatome graft was used, which was caused to adhere to the skull by fibrin fixation. The total period of hospitalization was 78 days. It is the authors' opinion that this represents the best modern management of the denuded skull.

For the wound seen immediately they suggest a method of splitting the scalp and using the outer layers as a free graft, which they hope may in the future provide victims of total avulsion with a hair bearing coverage for the skull. The application of blood plasma and thrombin topical solution seems an excellent method of fixation.

Plant managers should insist that women working around machinery protect their hair with hair nets.
HARRY W. FINK, M.D.

Giunchi, G.: Temporomaxillary Actinomycosis Caused by Anaerobic Actinomycetes of the Wolff-Israel Type, and Cured by a Combination of Sulfa Drugs and Roentgen Therapy (Attinomicosi temporo-mascellare, da attinomicete anaerobio del tipo Wolff-Israel, guarita con trattamento combinato sulfamidico e roentgenterapico). *Polidinico*, sez. prat., 1946, 53: 354.

The author treated temporomandibular actinomycosis in an 18 year old student with sulfamethylthiazole followed by roentgen therapy. The patient had a voluminous tumefaction in the right masseter, parotid, and temporal regions with an indistinct outline and of hard elastic consistency; there was also a fistula present. The alveolar portion of the lower jaw was intact and the regional lymph glands were normal. A culture of aspirated fluid disclosed anaerobic fungi of the Wolff-Israel type. Complement deviation tests were positive. The intradermal reaction with actinomycotic antigen was positive.

No amelioration could be obtained with potassium iodide. Three grams of sulfamethylthiazole were administered daily for 4 days, and 2 gm. per day were given on the following 7 days. After a 5 day interval the entire course was repeated. The tumefaction markedly diminished in size, the secretion disappeared, and a cicatrization of the fistula took place. Bacteriologic examination of aspirated fluid gave negative results; the pains and trismus disappeared.

Four months later a small tumor was still present, but bacteriologic examination gave negative results.

Polyneuritis, which developed in the course of the sulfa drug administration, was attributed to the medication, and induced the author to abstain from the further employment of sulfa drugs. A dosage of 1,200 r. of x-rays were given and under the influence of this treatment the tumor disappeared completely. A check-up 3 years later showed no signs of recurrence.

JOSEPH K. NARAT, M.D.

Morales, E.: Osteomyelitis of the Sphenoid Bone (Osteomielitis del esfenoides). *Rec. clarr.*, 1946, 6: 1.

The author reports a clinical observation of a case of osteomyelitis of the sphenoid bone in a 14 year old boy who on February 15, 1943 had symptoms simulating those of influenza, high fever, pain on swallowing, and left otalgia. On the following day a small peritonsillar abscess was observed on the left

side; this was incised and a purulent secretion appeared. During the following days the patient's condition became worse; there was inflammatory edema involving the left half of the skull, neck, and face with symptoms of meningism, rigidity of the neck, Kernig's and Brudzinko's signs, papillary edema of the left side, and a leucocyte count of over 14,000.

A diagnosis of thrombophlebitis of the cavernous sinus, lateral sinus, and left jugular vein was made and the patient was given 8 gm. of sulfa drugs daily for 10 days. A large tumefaction at the level of the left parotid gland was incised but no pus was found. There were a sequelae after the intervention: a facial paresis and a salivary fistula.

Three months after the patient was first seen he had a crisis of the epileptic type with loss of consciousness. No abnormality could be found after x-ray examination of the skull. Seven months after the symptoms began the local edema increased to extend to the eyelids and the patient had exophthalmos.

Again the local symptoms regressed after sulfa drug therapy but later the edema and pain localized in the right temporal region and occurred in the superior eyelid of the same side. The tumefaction was incised and a periostitis without pus was found. For the next 8 months there was persistence of the fronto-temporal edema, exophthalmos, and fistula of the left external orbital angle. The pus cultured was positive for the staphylococcus aureus. Occasionally bone fragments were drained through the nose and some of the secretion was eliminated posteriorly to the pharynx.

After the symptoms persisted for 1½ years the patient was given 500,000 units of penicillin. Later he was given a total of 5 million units of penicillin. Definite regression of the edema and exophthalmos was then observed. WILLIAM E. RICKETS, M.D.

Gerry R. G., and Sangston, R. E.: Congenital Mandibular Deformities In Newborn Infants. *Am. J. Orthodont.*, 1946, 32: 439

Congenital mandibular deformities in newborn infants have been frequently found but infrequently described. These deformities have been mentioned in the pediatric literature but not in the dental literature. Because of the possible confusion between these deformities and dislocation or fracture of the mandible, the authors present a small series of cases to illustrate how mandibular deformities may occur.

Deviation of the jaw was found to be present in about 20 per cent of the newborn infants which they observed. The deformities were due to intrauterine pressure, and not to a genetic disturbance, since only 1 of identical twins had this defect.

By reconstructing the position of comfort, it is often possible to illustrate the position in utero; it is also important to search for other congenital defects which might require early treatment. In all cases the deformities caused no difficulty in nursing or feeding and they were corrected spontaneously by the end of the tenth week. NOAN D. FABRICANT, M.D.

Rushton, M. A.: Unilateral Hyperplasia of the Mandibular Condyle. *Proc. R. Soc. M., Lond.*, 1946, 39: 431.

Hyperplasia of the mandibular condyle was first described in 1836 and up until 1936 about 17 cases had been reported. Several have since been added and this report includes 3. The condition makes itself apparent sometime between the ages of 10 and 30. Growth of the mandible occurs from the condyle, the articular surface of which is covered by fibrous tissue with precartilaginous tissue and cartilage and beneath this bone in the process of ossification is found. The formation of cartilage and its replacement by bone normally stops at about the age of 20.

The author reviews the various cases already recorded and presents the opinion that the condition is due in most instances to an abnormal continuance of growth at the condylar surface which leads to the formation of an elongated narrow neck so long as the natural process of remodelling of the neck persists. The coronoid process does not become enlarged. The chin projects forward and to the opposite side, which causes malocclusion of the teeth. The etiology is not known.

The most successful treatment has long been known to be excision of the condyle. This could be carried out as soon as the progressive nature of the deformity is definite, but condylectomy at a very early stage might make the operative side of the jaw permanently too short. JOUR R. LINDSEY, M.D.

Papper, E. M., and Rovenstine, E. A.: Anesthetic Management In Reconstructive Surgery of the Mandible. *Am. J. Orthodont.*, 1946, 32: 433.

Operative procedures upon the mandible pose special problems in anesthesia in direct proportion to the complexity of the surgical manipulations. Replacement of mandibular defects by bone grafting is difficult for surgeon and anesthetist alike.

The authors elaborate upon the principles concerned in anesthetic management and describe the results obtained in a series of 67 patients whose mandibular disabilities were traumatic in origin. Thirty-nine patients were anesthetized with nitrous oxide oxygen anesthesia aided by curare; 14 by the ether nitrous oxide sequence, 10 with ether and nitrous oxide, followed by scopolamine in the postoperative period, and 4 with pentothal (cocaine topical). All of the anesthetics were given intratracheally.

EYE

Sorsby, A., and Symons, H.M.: Amniotic Membrane Grafts In Caustic Burns of the Eye (Burns of Second Degree). *Brit. J. Ophthalm.*, 1946, 30: 337.

The authors discuss the use of grafts of human amniotic membrane in the treatment of caustic burns of the eye.

The main object, with this form of therapy, is to keep the inflamed surfaces apart. The ultimate

damage from caustic burns is usually greater than the immediate reaction. In the majority of cases, the burn is of second degree; usually, a localized superficial conjunctival lesion and a variable superficial corneal lesion are present. Neutralization of the caustic is of little value but excision of the damaged conjunctiva has been found valuable.

Prior to insertion of the graft, the eye is treated with penicillin—one drop of a concentration of 2,500 units per cubic centimeter every minute for a period of 10 minutes.

Dry human amniotic membrane is then folded to the correct size, in several layers. Silk is passed through each corner of the graft and through the bulbar conjunctiva, to suture the graft into place without covering too much of the corneal surface.

After 48 hours, when the bandage is removed, the graft is no longer visible, and it may be observed that the graft has become transparent and formed a layer over the conjunctival surface. The sutures are removed on the third or fourth day, and the eye is left open.

The authors conclude, from their experience in the cases of 30 patients with caustic burns of the eye which were treated by this method, that recovery is more rapid, and there are fewer corneal and conjunctival complications and fewer sequelae if the operation is performed immediately or, at most, 1 or 2 days after the injury.

JOSHUA ZUCKERMAN, M.D.

Duke-Elder, Sir S.: The Nutritional Aspects of Ophthalmology. *Irish J. M. Sc.*, 1946, No. 246, 177.

While a great volume of material on nutrition has appeared in recent years, commercial claims have often outstripped laboratory findings, and while extremes of starvation have been noted incident to the recent war it is the milder changes of a nutritional deficiency which have the more practical importance in normal life.

The only vitamins of importance ophthalmologically (as far as we yet know) are A, B, C, and D. The two ocular manifestations of Vitamin A deficiency are xerophthalmia and night blindness. The first entity was recognized, about the fifteenth century before Christ; but its cause was unknown; its relation to lack of Vitamin A was proved only after World War I. Recent work indicates that other factors besides Vitamin A are important in dark adaptation and that in many cases intake of this vitamin will not correct a night blindness.

The importance of riboflavinosis in causing keratitis has been grossly exaggerated by some authors. It is to be seriously considered only when newly formed vessels invade the cornea all around the limbus in both eyes, and the condition clears promptly on riboflavin therapy. The condition is extremely rare.

In spite of the reduction of Vitamin C found in cataractous lenses, no true causal relationship has been demonstrated.

The effect of avitaminosis on the central nervous system has been brought out during the recent war by the effect on those returned from German and Japanese prison camps where they had subsisted on a near starvation diet. A central scotoma develops, followed by a pallor of the optic disc but not complete blindness. If proper diet is obtained within 6 months from the onset most of the patients recover. The exact deficiency responsible is unknown although it is probably some part of the B vitamin.

It is suggested that if a profound state of avitaminosis can produce an optic neuropathy leading to optic atrophy or encephalopathy, minor subclinical degrees of deficiency may not be without effects in producing mental fatigue, irritability, apathy, depression, and neurasthenia. While the final answer is far in the future, it seems certain that eventually the nutritional basis of metabolic processes will be found to implicate the activity of every cell in the body more than is suspected today.

WILLIAM A. MANN, M.D.

Mann, I.: Exophthalmic Ophthalmoplegia. *Am. J. Ophthalm.*, 1946, 29: 654.

On the basis of experimental studies on the production of exophthalmos an attempt has been made to differentiate clinically between the effects produced by excess pituitary thyrotropic hormone and those caused by excess of thyroxine. Three sets of eye signs must be regarded: namely, (a) those due to overaction of unstriated muscle (lid retraction and exophthalmos abolished by anesthesia), (b) evidence of weakness of striped muscle (ophthalmoplegia), and (c) signs of increase in bulk (proptosis, chemosis, and edema of the lids). General changes, such as those in the basal metabolic rate and in weight, must also be considered. The possible action of the central nervous system through the hypothalamic structures as the stimulant or depressor of the pituitary gland must also be borne in mind.

In thyrotoxic ophthalmoplegia there is weakness of the extraocular muscles, with retraction of the upper lid and without any increase in the orbital contents. In thyrotropic exophthalmos, on the other hand, it is considered that there is ophthalmoplegia as well as proptosis and the eyeball cannot be pressed back nor moved freely within the orbit. There may be complication of the two types, but from a clinical standpoint it is perhaps simplest to consider lid retraction as a sign of excess thyroxine and defective eye movements as a result of excessive thyrotropic hormone.

The series of cases reported in this article were studied in an attempt to disentangle the parts played by the thyroid and pituitary glands, and the author has divided the 18 cases into various groups, as in some cases there was an overlapping of the two types of conditions. The following three groups are described:

1. Primary deficiency of thyroxine with compensatory excess of thyrotropic hormone secretion (4 cases).

2. Primary excess thyroxine as the initial symptom followed by thyroid atrophy or removal, and replacement with excess thyrotropic hormone (10 cases).

3. Excess thyroxine and excess thyrotropic hormone arising simultaneously (4 cases).

The cases are reported in detail. The most interesting feature of the treatment was the marked improvement following the use of thyroid extract in groups 1 and 2. Of course, thyroid cannot be used in the patients in Group 3, who must still be treated symptomatically. In addition to the thyroid therapy, tarsorrhaphy was found useful in treating some of the cases in Groups 1 and 2.

Ida Mann has made a very valuable contribution to the therapy of exophthalmic ophthalmoplegia.

WILLIAM A. MANN, M.D.

Siniscal, A. A.: Oculoglandular Tularemia. *Am. J. Ophthalm.*, 1946, 29: 698.

The author reports 3 cases of oculoglandular tularemia with a typical clinical picture in each. In each case a domestic animal was thought to be the agent of transmission.

The article includes an excellent summary of the literature on the subject. Emphasis is made on the importance of the differential diagnosis from other forms of oculoglandular pathology and the place of the blood agglutination test in tularemia. Ordinarily the latter is not positive until after 10 days. Although fatal in many animals, tularemia of all forms is said to be fatal in only 5 or 6 per cent of the cases in human beings.

Treatment of oculoglandular tularemia consists in the local use of mild germicidal preparations, Foshay's serum, artificial fever therapy, and convalescent serum in severe cases. Streptomycin has been reported to be effective against the disease in laboratory animals.

Roenne, G.: Local Treatment of Intrabulbar Infections. Treatment of Staphylococcal Panophthalmitis by the Intrabulbar Injection of Penicillin. *Brit. J. Ophthalm.*, 1946, 30: 405

Although the author's investigations dealt with only a single form of bacterium it may be assumed that penicillin has the same bactericidal action on other microbes usually encountered in infected perforating lesions of the eye. Moreover, in sufficiently large doses the effect of penicillin is practically unlimited even for the most intense infections. The intrabulbar injection of penicillin results in a few advantages not obtained with general treatment; for example, the bactericidal concentration of penicillin is maintained for a long period of time (from 16 to 24 hours); only small quantities of penicillin are necessary; and the penicillin will attain a satisfactory concentration in the vitreous, which result will not follow general penicillin treatment.

Roenne concludes that for intrabulbar, especially intravitreal inflammations, the injection of penicillin into the vitreous is the best form of therapy to date.

In therapeutic concentrations of between 100 and 500 Oxford units it is practically harmless and is extraordinarily effective compared with injection of other substances, such as chloramine-T, and with other forms of their application. The effectivity is directly proportional to the concentration of penicillin, the result being dependent only on the number of bacteria in the eye and not on the interval between the inoculation and the treatment.

JOSHUA ZUCKERMAN, M.D.

Cutler, N. L.: Transplantation of the Human Vitreous; A Preliminary Report. *Arch. Ophthalm.*, 1946, 35: 615.

This is the first published report on the transplantation of human vitreous for the correction of vitreous opacities. Previously, efforts have been made to produce a clearer medium by injecting normal salt solution and air. Three cases were treated in which there was a large amount of unabsorbed vitreous hemorrhage; 2 of the cases were traumatic and 1 was spontaneous. There was good light projection and the intraocular tension was normal.

A small scleral incision with the cataract knife is made in the equatorial region after a preliminary 0000 silk mattress suture is effected. An 18 gauge needle on a 5 c.c. syringe is introduced directly into the vitreous and approximately 1.5 c.c. of vitreous are withdrawn. Approximately 2 c.c. of clear vitreous from a freshly enucleated eye are then injected with a syringe through the needle and the suture is tied.

In 2 of the 3 cases the procedure was successful. In 1 case the visual acuity improved from light perception and projection to 20/60 with correction; in the second the improvement was from light perception to 20/30 with correction; and in the third the result was a failure and it was believed that the vitreous was injected behind the retina because of detachment of the latter.

From his experience with this procedure the author believes that from 1.5 to 2 c.c. of vitreous are the maximum which can be withdrawn from the recipient eye. The blood group does not appear to be significant. The pathological vitreous appeared to be more fluid than normal but it is not known whether this was caused by the transplanted vitreous. There was a moderate reaction after the transplantation but no foreign protein reaction. The tension in all 3 cases returned to normal in a short time and remained so.

It is believed that this method offers new possibilities in the surgical treatment of the vitreous.

WILLIAM A. MANN, M.D.

Elwyn, H.: Heredodegenerative Diseases of the Retina. An Attempt at Classification. *Arch. Ophthalm.*, 1946, 35: 662.

Abiotrophy, or heredodegenerative disease, of the retina is classified by the author under the diseases of the central nervous system characterized by a specific loss of neural tissue as a result of hereditary influences. He differentiates these from the heredo-

constitutional diseases in which there is a hereditary vital defect but no progressive loss of tissue so that the disease remains stationary.

Heredodegenerative diseases of the retina may occur:

1. As primary disease of certain retinal elements (retinitis pigmentosa, heredodegeneration of the macula).

2. In association with another similar disease of the retina, such as macular degeneration associated with degeneration of the peripheral neuroepithelium.

3. In association with hereditary diseases of the central nervous system (Laurence-Moon-Biedl syndrome).

4. As part of a hereditary disease of the central nervous system (amaurotic familial idiocy).

5. As a part of a widespread systemic disease involving many organs (Niemann-Pick disease, tuberous sclerosis).

These conditions may also be classified according to the retinal elements primarily involved and the following classification is given:

A. Originating in the elastic layer of Bruch's membrane.

1. Disciform degeneration of the macula (Kuhnt-Junius type)

2. Angioid streaks in the fundus

(a) Occurring alone

(b) Occurring in association with pseudoxanthoma elasticum (Grönblad-Strandberg syndrome)

B. Originating in the pigment epithelium

1. Hyaline or colloid bodies (drusen) of the basal layer of Bruch's membrane

C. Originating in the neuroepithelium

I. In the central, or macular area

1. Heredodegeneration of the macula, including the infantile, juvenile, adult, presenile, and senile types, occurring (a) alone, or in association with (b) degeneration of the peripheral neuroepithelium, (c) atrophy of the optic nerve, (d) color blindness, and (e) mental deterioration

II. In the extramacular neuroepithelium

1. Retinitis pigmentosa, occurring (a) alone, or in association with (b) degeneration of the macula, (c) color blindness, (d) deafness, (e) mental deterioration, (f) the juvenile type of amaurotic family idiocy, and (g) the Laurence-Moon-Biedl syndrome.

III. Heredoconstitutional diseases of the neuroepithelium

1. Retinitis punctata albescens
2. Congenital night blindness without changes in the fundus
3. Congenital night blindness with grayish white discoloration of the fundus (Oguchi's disease)
4. Color blindness

IV. Heredodegeneration of doubtful origin but standing in some relation to degeneration of the neuroepithelium

1. Gyrate atrophy of the choroid and retina

2. Choroideremia, a heredoconstitutional disease

D. Originating in the ganglion cells

1. Infantile type of amaurotic familial idiocy (Tay-Sachs disease), affecting only the ganglion cells

2. Juvenile type of amaurotic familial idiocy, involving the neuroepithelium in addition to the ganglion cells

3. Niemann-Pick disease

E. Involving the nuclear layers

1. Peripheral cystoid degeneration in senile and presenile eyes

2. Widespread cystoid degeneration, forming the basis for rupture of the retina with hole formation and consequent retinal detachment

3. Retinitis circinata

F. Involving the nerve fiber layer

1. Tuberous sclerosis, a widespread heredo-degenerative disease, causing the production of abnormal cells and tumors in this layer.

EAR

Shambaugh, G. E., Jr., and Juers, A. L.: *Surgical Treatment of Otosclerosis; A Preliminary Report on an Improved Fenestration Technique. Arch. Otol., Chic., 1946, 43: 549.*

The two year hearing results of the fenestration operation may be considered the permanent hearing results.

Experimental studies of the fenestration operation in the monkey have brought out certain factors that influence the osteogenesis tending to close the fistula. The application of these factors to the human operation has reduced the incidence of failure due to bony closure to less than 5 per cent in patients tested after two years.

The adoption of features to improve the mobility of the tympanomeatal skin flap between the tympanic membrane and the fistula has increased the average number of decibels gained from 28 to 30.

NOSE AND SINUSES

Weille, F. L.: *The Problem of Secondary Frontal Sinus Surgery. Ann. Otol. Rhinol., 1946, 55: 372.*

Weille reviews the problem of secondary frontal sinus surgery on the basis of experiences with 276 cases of frontal sinus conditions treated by surgery. A total of 862 operations were performed upon the nasal cavities, sinuses, and cranium, including plastic and brain procedures. Many of these operations

were done outside of as well as in the Massachusetts Eye and Ear Infirmary. Of these, 447 were done directly or externally upon the sinuses. Some of the patients were referred to the Infirmary as a last resort; 95 had more than 1 external operation on one or both frontal sinuses. The highest number of operations on 1 patient was 9.

Aside from the deformity which it produces, the obliterative operation results in a not unmixed blessing. Thirty-three of 123 patients treated by this method required further frontal surgery. The repair of the deformity required an average of about a year in 71 patients. The longest time required for such repair was 5 years and 3½ months. Only 29 per cent of the 276 patients had no osteomyelitis and multiple nonobliterative operations (totalling 77) on the frontal sinus or sinuses.

A basic knowledge of applied surgical anatomy, and a fundamental understanding of epithelial, connective tissue, and bone responses in wound healing in the frontal region are helpful in evading repeated frontal operations. Simple closure of the nasofrontal surgical opening is a paramount cause for the necessity of secondary frontal sinus surgery. Some surgical methods for dealing with this problem are outlined.

The avoidance or simplification of surgical methods in the treatment of frontal sinus disease may be greatly aided by chemotherapy, especially with penicillin. However, chemotherapy is not a substitute for surgical fundamentals. Only 1 death occurred in the series after sulfadiazine and penicillin were used.

MOUTH

Gaston, E. A., and Tedeschi, C. G.: Adenolymphoma of the Parotid and Submaxillary Salivary Glands. *Ann. Surg.*, 1946, 123: 1075.

Tumors composed of a combination of epithelial and lymphoid tissue arising in or near the parotid gland and occasionally in the submaxillary salivary gland have been reported with increasing frequency. The terminology of these tumors is confused by the fact that they have been reported under a number of different names, of which the following may be enumerated: papillary cystadenoma lymphomatousum, cystadenoma lymphomatousum, adenolymphoma, papillary adenolymphoma, papillary cystadenoma in the lymph glands, branchiogenic cystadenolymphoma, branchiogenic adenoma, cylindrocellular branchiogenic adenoma, oncocytoma and Warthin's tumor.

This varied nomenclature is, in part, a reflection of the numerous attempts that have been made to account for their origin. From a review of the literature and a study of the cases presented it is evident that not all tumors having this same fundamental structure are identical in either histological pattern or clinical behavior. Thus, a group of tumors exists and it is the purpose of this communication to attempt to clarify the nomenclature

by presenting a working classification based on morphology and clinical behavior. Four new cases are presented, 1 of which is malignant.

Two cases of papillary cystadenoma lymphomatousum of the parotid salivary gland and 1 case of a purely cystic variety of the same tumor are presented. These are rare tumors and occur 4-5 times more frequently in men than in women.

The recorded theories of the histogenesis of these tumors are reviewed. The authors agree with Warthin that they probably arise from epithelium of the embryonic pharyngeal endoderm or upper respiratory tract displaced to the region of the parotid gland.

Papillary cystadenoma lymphomatousum and its histological variants are probably always benign. The results of surgical excision are excellent.

A morphologically and clinically malignant tumor of the parotid gland consisting of a combination of glandular and lymphoid tissue is presented. Its histogenesis is discussed.

A classification of adenolymphomatous tumors of the parotid and submaxillary regions is suggested.

JOHN F. DEARM, M.D.

Archer, W. H., and Morris, R. D.: A Survey of Oral Carcinoma at the Columbia-Presbyterian Medical Center. *Am. J. Orthodont.*, 1946, 32: 333.

The authors review 203 histories of oral carcinoma collected during the past 25 years at Columbia-Presbyterian Medical Center. The lesions occurred in the tongue, floor of the mouth, cheek, palate, and alveolar gingivae. Eighty-five per cent occurred in males, and 78 per cent were found in patients between 45 and 74 years of age. Statistics showed an apparent predisposition in individuals of Irish extraction and a lessened tendency in negroes. Thirty-two per cent of the lesions on the anterior tongue were associated with syphilis; 15.8 per cent were associated with leucoplakia, 11 of these patients also having syphilis. Smoking was found to be negligible as an extrinsic predisposing factor. Fifty-seven per cent of the patients gave no evidence of any of the possible contributing factors, such as leucoplakia, trauma, and irritation. A five year follow up was possible in 135 cases. Surgical treatment was given in 25, radiation therapy in 101, and a combination of the two, in 20. The five year survival rate was 25 per cent and did not vary according to the location of the primary lesion.

JOHN R. LINDSAY, M.D.

PHARYNX

Hollender, A. R.: The Nasopharynx. A Study of 140 Autopsy Specimens. *Laryngoscope*, 1946, 56: 181.

The primary objective of this article is to record the pathological findings in 140 autopsy specimens of the nasopharynx.

The anatomy, histology, and pathology are discussed, and the pathological findings in 140 autopsies are tabulated. There were 24 cases of pulmonary tuberculosis among the total number and 18 of

these gave definite gross or microscopic evidence, or both, of tuberculosis of the nasopharynx.

As far as lymphoid hyperplasia of the nasopharynx is concerned, this study revealed the frequent incidence of hyperplasia of the nasopharyngeal or of the tubal tonsils, or both, in older persons, even in the sixth or seventh decades of life.

While 10 pharyngeal bursae were found among the 140 specimens, histological examination of several specimens revealed the fact that the characteristic symptoms of pharyngeal bursitis may be simulated by an inflammatory or infectious process in the median recess.

JOHN F. DELPH, M.D.

Nelvert, H., Pirk, L. A., and Engelberg, R.: Late Secondary Tonsillar Hemorrhage; Studies of Ascorbic Acid. *Arch. Otolaryng.*, Chic., 1946, 43: 563.

Two comparable series of patients undergoing tonsillectomy were studied. The plasma levels of vitamin C of the control series were determined before and after operation. The preoperative concentration of ascorbic acid was subnormal in more than half of the patients and there was a decrease in the vitamin C content postoperatively in the majority of those whose original values had been normal. Most of the hemorrhages occurred in the patients with vitamin C deficiency. The patients of the second series were saturated with ascorbic acid, and in these the incidence of hemorrhage was significantly reduced.

The patients of both series received liberal amounts of acetylsalicylic acid. Since hypoprothrombinemia caused by salicylate has been shown to be one of the most important etiologic factors of secondary tonsillar bleeding, the beneficial results observed with ascorbic acid were thought to be indicative of a protective effect exerted by this vita-

min against drug-induced prothrombinopenia. Experiments carried out in this direction bore out this suspicion. Evidence is presented that vitamin C prevents salicylate-induced hypoprothrombinemia. This effect is believed to be due to the detoxifying action of ascorbic acid.

In a subsequent report the results attending the combined administration of vitamins C and K will be presented.

NECK

Dargent, M., Guinet, and Bonniot, R.: Benign Attacks of Goiter and a Severe, Heterogenous Type of Cancer. Clinical and Pathogenic Considerations (Poussées goitreuses bénignes et cancer hétérogène grave. Réflexions cliniques et pathologiques). *Presse méd.*, 1946, 54: 305.

Brief case histories are given of patients in whom the development of a colloid and apparently involuntary type of goiter followed the development of a cancerous condition. In 1 patient the malignant growth proved to be an achromatic nevoid cancer, in another, an atypical epithelioma of the breast; in the third, a recurrent spinocellular epithelioma following a Wertheim operation, and in the fourth, an atypical epithelioma of the breast which flared up again locally after removal of the goiter.

The author believes that this succession of cases with such an association of goiter and carcinoma is more than a coincidence and suspects the presence of cancerogenic (endogenous or exogenous) thyrotropic substances in these patients, which act as a chronic toxic stimulus on the thyroid gland. However, by this supposition the author does not mean to attack the commonly held conviction that the thyroid gland exercises a restraining influence on cancer.

JOHN W. BRENNAN, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Robertson, E. G.: A Method of Encephalography. *Surgery*, 1946, 19: 810.

As any neurological surgeon realizes, encephalography by the usual lumbar puncture method may on occasion fail completely in its results, although there is no obstruction to the passage of either air or fluid in the posterior cranial fossa. According to Robertson, this disappointing outcome of a procedure which may be fruitless and distressing to the patient may be obviated by definite positioning of the head during the procedure, so that with amounts as small as 25 c.c. of oxygen the ventricles may be filled, or the subarachnoidal spaces and basilar cisterns well outlined in a selective manner.

The author uses filtered oxygen and the two-needle method, and cautions that at all times the gas must be introduced slowly. His patients are given omnopon, $\frac{1}{2}$ gr., and scopolamine hydrobromide, from 1/150 to 1/100 gr., if adults, and children receive either paraldehyde rectally or ether inhalation. During the introduction of the gas the patient sits with the head positioned in front of the x-ray screen. Since the injected gas rises against gravity to seek the highest level in the fluid spaces about the upper spinal cord, the patient's neck should be fully flexed when the introduction of gas is begun, so that there may be maximum filling of the cisterna magna and the subarachnoidal spaces dorsal to the cervical cord. Then, with gradual extension (dorsiflexion) of the neck, the gas will enter the fourth ventricle and aqueduct when the angle of extension is from 90 to 80 degrees. Serial films may then be taken as the further introduction of gas and further extension of the neck proceed slowly. According to the author, gas usually enters the lateral ventricles at about the stage of 60 degrees of extension. The volume of gas in the ventricles increases progressively as the head is dorsiflexed, and is maximal when the head is erect. If, in the beginning, the patient's neck is dorsiflexed, the gas rises anterior to the cervical spinal cord to enter the subarachnoidal spaces anterior to the medulla and to pass, at higher levels, into the basal cisterns.

Detailed instruction is given for the exact positions according to the angles of flexion and extension of the neck for selective filling of the ventricular system, the various basilar systems, the cerebral subarachnoidal spaces, and the fluid filled spaces of the posterior fossa.

JOHN MARTIN, M.D.

Robertson, R. C. L., and Peacher, W. G.: The Management of Late Head Injuries. *Ann. Surg.* 1946, 124: 40.

A report is made of the experiences with tantalum in the repair of 254 cranial defects. The great ma-

jority of the patients were those with craniocerebral injuries, although a few had other cranial conditions requiring bone removal.

A one stage, operative procedure is recommended, with fashioning of the tantalum plate at the operating table. In traumatic cases, the dura has frequently been opened to remove cerebrodural or cortical scars, and, frequently, metallic foreign bodies. Tantalum foil has been used to cover the brain in cases in which the dura has been entered. It is believed that this may overcome further meningocerebral cicatrices.

All of the patients were subjected to pneumoencephalography previous to the operative procedure, in order that the presence of ventricular shift, porencephaly, internal hydrocephalus, and other conditions which would facilitate the operative procedure could be determined.

The post-traumatic syndrome was not encountered as frequently in the severe, penetrating gunshot wounds as in the milder cases of concussion.

Various medications were tried in the treatment of the post-traumatic symptoms of headache and dizziness, but with very little improvement in the results.

It was concluded that pneumoencephalography offers very little relief from post-traumatic head pain. It had been advocated as a therapeutic measure previously.

It was concluded that there was no specific medical or surgical treatment for the numerous manifestations of the post-traumatic syndrome. Intelligent, judicious management, with reassurance, early ambulation, mild sedation as indicated, and an intensive reconditioning program have given more favorable results than any other methods employed.

HOWARD A. BROWN, M.D.

Verneti, L.: The Behavior of the Hematological Picture in Comotio Cerebri (Sul comportamento del quadro ematologico nella commozione cerebrale). *Minerva med.*, Tor., 1946, 1: 134.

Ten cases of commotio cerebri are reported. In each case a blood study was made at the time the patient entered the hospital, and followed by subsequent daily examinations. Only such cases are included in this report in which the clinical symptomatology and subsequent course left no doubt as to the diagnosis of commotio cerebri, and excluded such possibilities as contusion or compression. In 6 instances the roentgenographic examination evidenced nondepressed fractures of the vault or of the base of skull; in 3 there was a simple condition of commotio cerebri, uncomplicated by cranial lesions. The remaining patient was not examined with the x-rays.

The initial blood examination, made in every instance within 12 hours after the injury, showed a variation of from 10,000 to 24,000 leucocytes; in 2

cases the corresponding counts were 21,400 and 21,600, respectively. In the following days the white count varied from case to case. In some instances the count returned to normal within 3 days; in others the count increased to attain its peak after 6 or 8 days. In 2 instances death occurred after 36 and 12 hours, respectively, and in these the count rose steadily up to the very end. A diminution in the number of eosinophils and a lymphopenia amounting to about a half of the usual count was constantly noted in these cases. In some cases a few immature elements of the myeloid series appeared.

The author believes that there is a center somewhere in the brain stem which is concerned in the regulation of the cytologic composition of the blood, particularly as regards the behavior of the white cell count; that this is the part of the brain concerned in commotio cerebri; and, therefore, that the behavior of the white cell count may be used in the prognosis in cases of uncomplicated commotio cerebri.

JOHN W. BRENNAN, M.D.

Ingraham, F. D., and Scott, H. W., Jr.: Craniopharyngiomas in Children. *J. Pediat.*, St. Louis, 1946, 29: 95.

This excellent article deals with the experience of the authors with 16 children who were treated for craniopharyngioma at the Children's Hospital and Peter Bent Brigham Hospital in Boston during the period from 1932 to 1945. Thirteen per cent of the reported intracranial tumors in children are craniopharyngiomas, and among the 2,000 verified intracranial tumors in the Cushing series, 4.6 per cent were such tumors.

After a clear description of the embryology and histological types of these tumors, the authors discuss the pathological physiology of craniopharyngiomas according to the four main disturbances which they produce: visual changes, intracranial hypertension, hypophyseal disorders, and hypothalamic dysfunction. They give 2 detailed case histories from their own files, and discuss the diagnosis of these tumors, a generally not too difficult process, which is based directly upon the physiological disturbances just mentioned.

Since these tumors are benign in nature, theoretically, at least, it is altogether logical that they should be treated by surgical means, and the results of the authors as well as of others who have had experience with a large series bear out this belief. Complications of surgery may arise from the leak of the highly irritating cyst fluid into the general ventricular system, and the persistent tendency toward arterial hypotension and collapse during and after surgery which must be combated with the proper administration of whole adrenal gland extracts. In those patients with long survival periods following the original surgical treatment but with recurrence, reoperation is the method of choice. When surgery has been tried but recurrence has been rapid, it may be safest and more effective to administer roentgen therapy to the tumor.

JOHN MARTIN, M.D.

Luft, R.: The Treatment of Cushing's Syndrome. *Acta med. scand.*, 1946, 124: 227.

It is the author's opinion that the syndrome commonly called Cushing's syndrome is not due primarily to the more or less typical cytological change in the pituitary gland, with occasional actual basophil adenoma formation, but rather that the disease is due to adrenocortical hyperfunction. Before any treatment or surgical interference is instituted, it must be determined whether there is an adrenal tumor present, and this is done by determining the 17-ketosteroid values, which are found to be increased in the presence of an adrenocortical tumor. Such tumors should be removed, and proper endocrine replacement therapy should be instituted. When no adrenal tumor can be found, treatment may consist of extirpation of a pituitary adenoma, if this type of tumor can be discovered, or one of several other forms of treatment, such as irradiation of the pituitary gland, irradiation of both the pituitary and the adrenal glands, the administration of estrogenic substance, and, in the experience of certain authors, the injection of androgenic hormone.

The author's personal experience with this syndrome consists of 7 cases, in 5 women and 2 men whom he treated mainly by short series of irradiation to the pituitary gland, repeated at 3 month intervals. He gives full case histories, and his results certainly seem to be as successful as those reported by other authors with other forms of treatment or with the same general plan of treatment. He obtained no satisfactory results with the use of estrogenic substance. He did not find that irradiation of the pituitary gland caused any noticeable ill effect on the normally functioning portion of the gland. His opinion and results are not in keeping with the opinion of Thompson and Eisenhardt (1943), who stated that roentgen treatment has failed in the majority of cases.

JOHN MARTIN, M.D.

Schleizinger, N. S., Alpers, B. J., and Weiss, B. P.: Suprasellar Meningiomas Associated with Scotomatous Field Defects. *Arch. Ophthalm.*, Chic., 1946, 35: 624.

Four cases of suprasellar meningioma are reported with particular reference to the eye findings and visual field changes. Emphasis is laid upon the occurrence of such visual loss with scotomas in the visual fields, associated with more or less severe headaches. The rapidity of onset of these symptoms may simulate, in the early stages, the clinical picture of retrobulbar neuritis and present some confusion in the diagnosis.

Completely uniform alterations in the visual fields do not occur as the result of suprasellar lesions. The early scotomatous field defects were demonstrated in the authors' 4 patients with suprasellar meningiomas. Scotomatous field defects serve as a clue to the existence of prechiasmal or chiasmal lesions, by combining with a peripheral encroachment on the visual field at some point so as to produce an expanding sector defect.

In the prechiasmal syndrome associated with suprasellar meningioma, the outstanding symptom was impairment of vision, rapidly progressive and affecting the 2 eyes successively rather than simultaneously, with slight pallor of the discs in the early stage, followed by subsequent optic atrophy. This clinical picture coupled with scotomatous changes (particularly expanding scotomatous defects) points toward a suprachiasmal lesion. The early recognition of this syndrome, particularly with reference to the meningiomas, is of importance in view of the relatively benign character of the tumor encountered.

HOWARD A. BROWN, M.D.

SPINAL CORD AND ITS COVERINGS

Frugoni, P., and Pozzi, A.: Vertebral Echinococcosis (Echinococcosi vertebrale). *Policlinico, sez. chir.*, 1946, 53: 1.

The more significant of the 2 cases here reported was that of a 44 year old married woman who had been bedridden for 6 months when 16 years of age because of pains in the lumbar region. When 38 years old a thoracentesis was done, and later a thoracotomy, for echinococcosis of the upper lobe of the right lung. Three years later a spastic paraplegia occurred rather suddenly, which soon became flaccid in type. The laboratory disclosed an evident disassociation between the albumin (2.20%) and the cell count (0.1%) of the spinal fluid; lipiodol injection revealed a spinal block with the lower level at the seventh dorsal vertebra and the x-rays portrayed some rather indefinite areas of rarefaction in the body of the fifth dorsal vertebra.

During the laminectomy the laminae of the sixth and seventh dorsal vertebrae seemed more porous than normal. The completed laminectomy (D5 to D8) uncovered a huge cystic formation completely enclosing the dural sac and cross partitioned by fibrous matter into three subdivisions. These subdivisions contained a small amount of colorless fluid and about 70 tiny various sized cysts filled also with colorless fluid. The sac also contained some gelatinous material (probably deteriorated cyst walls) but no trace of chitinous material. The compressed cord was pushed anteriorly and to the left. The main sac was in communication, through the two foramina between the sixth and seventh and the seventh and eighth dorsal vertebrae, with what appeared to be an extension of the process into the right paravertebral region at this level.

Without opening of the dura, as much as possible of the sac and cysts were removed and that part of the sac which was adherent to the dura was formalized. The condition of the patient seemed to forbid following the extensions out through the intervertebral foramina into the chest region. At autopsy, about 3½ months later, the compressed condition of the cord had not changed.

In seeking an explanation for the odd findings in this case, the authors subscribe to the teachings of Grisel and Deve, whose views were expounded in the

Revue de Chirurgie (1929, 67: 464). They believe that in this case the primitive lesion developed in the body of the vertebra—as suggested by the roentgenogram of the fifth dorsal vertebral body—in the form of a multilocular invasive microcystic lesion which penetrated into the spinal canal through an aperture or apertures so insignificant as to escape detection. The resultant sac in the spinal canal, which was under pressure and enclosed in a firm osseous cavity, then sought a safety valve by boring out through the intervertebral foramina into the paravertebral region of the chest.

The authors emphasize the presence or absence of chitinous material in the intraspinal sac. In the latter contingency, occurring in the multilocular form with lack of a mother cyst, the laminectomy should be as extensive as possible and the pathological process widely removed. It is thought that in the presence of a paravertebral hydatid involvement, whether subpleural or retroperitoneal, or mediastinal or involving the paravertebral muscles back of the spinal column, the physician should always consider that this process might be secondary to a primitive echinococcal invasion of the vertebra and act accordingly.

The authors report a second case of intrarachidial echinococcosis without x-ray or other evidence of involvement of the bones of the spinal column and without extrarachidial extension, but with a history of a retroperitoneal echinococcus cyst, which was removed surgically. Three years later, symptoms of paraplegia appeared and progressed rapidly. At laminectomy an intrarachidial cyst was uncovered; it extended from the twelfth dorsal to the second lumbar spinal segments and communicated with the interior of the dural sac extrinsically, sitting astride, so to speak, the spinal cord itself.

This sac, filled especially in its intradural extension with daughter cysts and mildly suppurating, was removed as widely as possible. Following the operation the patient regained his ability to walk and his condition improved generally, but he died about a year later.

JOHN W. BRENNAN, M.D.

Silverman, S.: Vascular Tumors of the Spinal Cord Associated with Skin Hemangiomas. *Brit. J. Surg.*, 1946, 33: 397.

Although Sturge-Weber's disease has become rather well known, an analogous combination of vascular tumors of the spinal cord with corresponding segmental skin nevi has been less commonly observed. At the Midland Nerve Hospital in Birmingham, England, a case of this nature was studied and verified. The patient was a 47 year old female with an extensive congenital nevus involving the left side from the fifth cervical to the tenth thoracic dermatome. Eleven months before hospitalization, following a fall and laceration of the buttocks, the patient had developed a sudden paraparesis with an indefinite sensory level in the thoracic area. Acute exacerbations occurred on 2 occasions and finally resulted in a paraplegia with a definite sensory level.

Following a lipiodal myelogram a laminectomy was performed which revealed a mass of tangled blood vessels in the epidural space. After an uneventful convalescence deep roentgen therapy was given with improvement in the clinical picture.

Wyburn-Mason believed that there was no direct affective relationship between the two sites, but their coexistence was due to a developmental disorder of the whole neuromyodermatome. Usually they are in comparable segments of the spinal cord and integument. Oftentimes the spinal cord involvement is not recognized until hemorrhage occurs or the tumors increase in size. This frequently takes place in apoplectiform stages. The present case and those in the literature are of a simple hemangiomatous nature rather than hemoblastomatous.

JACK I. WOOLF, M.D.

Lindsay, J. S. B., and Falconer, M. A.: Painful Phantom Limb Treated by High Cervical Chordotomy. *Brit. J. Surg.*, 1946, 33: 302.

Pain occurring in association with phantom limbs has long been a difficult medical problem. However, in the past decade it has become well recognized that more than one factor or type of pain may be present. The psychological factors frequently present are not discussed in this article.

The authors believe that there are two main types of organic pain, the most common type being due to irritation of the peripheral nerve endings. This may involve either the peripheral sensory nerve fibrils or sympathetic nerve fibrils involved in or about the cicatricial formation. In the former, local resection or nerve block will relieve the pain, while in the latter a sympathetic block or sympathectomy will relieve the pain. When neither type of block will relieve the pain, it is thought that the pain impulses arise in the dorsal horn cells of the spinal cord, and hence section of the spinothalamic pathway or ablation of the cortical sensory area will alleviate the pain. Chordotomy should be preferable to cortical ablation since it removes only the pain and does not interfere with cortical sensory perception, and therefore it permits the use of the stump for prosthetic devices.

Sectioning of the pain pathways to the lower extremity is easily performed by a high thoracic anterolateral chordotomy. However, in the past it has been difficult to perform a similar section for pain in the upper extremity. The authors incorrectly state that mesencephalic tractotomy (Walker) and medullary tractotomy (Schwartz and O'Leary) have failed to produce a sufficiently high level of analgesia. This is derived from their first report, for later publications have shown that high levels of analgesia have been obtained. In a discussion of Walker's paper (*Arch. Neur. Psychiat.*, 1942) both Grant and Peet give some of their results with a high cervical chordotomy at C₂. Although a satisfactorily high level of analgesia was obtained in some cases, the results were not uniformly good in larger series. Anterolateral chordotomy in the high cervical region midway between the nerve roots of C₁ and C₂ was

Fig. 1. Diagrammatic cross section of cervical cord to show extent of chordotomy.

performed by the authors on 2 patients. Both patients had been studied preliminarily by paravertebral and local nerve blocks without relief of pain. Complete relief of the pain was obtained without affecting the awareness of the phantom limb.

A note of caution is suggested in the report of the second case in which an ipsilateral hemiplegia was noted immediately after the sectioning. Fortunately, this cleared up in about an hour; however, the possibility of more permanent damage must be recognized.

The accompanying diagram shows the probable extent of the chordotomy.

PERIPHERAL NERVES

Bonola, A.: Brachial Plexus Paralysis from Gunshot Wounds (Le paralisi del plesso brachiale per ferite d'arma da fuoco). *Chir. org. movim.*, 1943, 29: 12.

Twenty-five cases of brachial plexus injury from wounding by firearms came under observation at the Rizzoli Orthopedic Institute in Bologna. Of these, 15 underwent exploratory operation. Seven of the operative cases are reported in detail, and diagrams, sketches, and actual photographs of the conditions encountered are given in the original article.

The incision used in every case was the one which was developed at this institute. It starts well up on the neck, extends vertically along the outer border of the sternocleidomastoid muscle, crosses the clavicle, and passes down toward the axilla along the deltoideopectoral sulcus. To this incision may or may not be added a transverse incision along the upper border of the clavicle. The clavicle was usually cut through toward its outer end and retracted in both directions with the aid of a sand bag under the scapula. Any injury to the blood vessels, of course, was given first attention (aneurysm, arteriovenous aneurysm) and then an attempt was made to assess and repair any injury of the nerves and trunks of the plexus itself. In some instances the nerves were not completely separated, but were compressed by the

conditions by a plethysmograph, is greatly influenced by emotional stimuli, drafts, and pain mediated through the peripheral sympathetic nerves. The reflex effects of heat and cold are ineffective in an extremity which has been subjected to a sympathectomy. After a sympathectomy an arteriosclerotic limb maintains a circulation comparable to that which could be obtained only in a warm, semitropical climate, the benefits of which are well known in the treatment of peripheral arteriosclerosis.

Another factor is the high vasomotor tonus in the lower extremity of man which helps to maintain the normal blood pressure. This tonus is least in a horizontal position, greater in a sitting position, and greatest in the erect posture. How such a postural vasoconstriction affects a diseased vascular bed is obvious. This factor is eliminated by sympathectomy so that the vasomotor tonus is not any higher when the patient is erect than when he is horizontal. Therapeutically this is analogous to rest in bed. Although intrinsic muscle tone is regained after a period, it has been shown previously that the venocapillary stretch produced by intermittent venous hyperemia is far more effective in the sympathectomized limb than in the limb with an intact sympathetic supply.

The striking relief of pain which is obtained in limbs following procaine block and sympathectomy,

whether due to thromboangiitis, arteriosclerosis, or embolic occlusion, is not completely understood. An ingenious theory postulated by Doupe states that cross stimulation occurs between efferent sympathetic nerves and the demyelinated, poorly insulated sensory axons which results in pain or even efferent vasodilatation. Another cause is suggested by the reflex vasoconstriction which occurs after pain. This operates in the case of ischemic neuritis, thrombosed arterial segments, or periarterial and lymphangitic inflammatory reactions, and is abolished by sympathectomy.

The effects of lumbar sympathectomy on the lower extremity are tabulated:

1. The limb warms faster and cools more slowly on direct exposure, and reflex effects of heat and cold are ineffective.
2. The high vasoconstrictor tonus in the sitting and standing position is abolished.
3. Vascular exercises such as intermittent venous hyperemia are more effective.
4. Cross stimulation between the sympathetic and demyelinated sensory fibers is prevented.

The excellent results in this small series are stated to be "due to the release of normal vasomotor tonus, which in turn insures an even blood flow uninfluenced by anything but the metabolic need of the tissues."

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Garven, H. S. D.: *Demodex Folliculorum in the Human Nipple. Lancet, Lond., 1946, 2: 44.*

Ten of 13 cases observed by the author showed the presence of a parasite corresponding in size and structural details to the *Demodex folliculorum*. The parasite may be found lying in the sebaceous material in the mouths of the sebaceous glands, with the head directed toward the living cells of the glands. In many cases, it is also found lying deep in the gland among the living cells with its head close to or almost touching the basement membrane of the gland. In this situation it may cause some reaction in the tissues surrounding the gland. Round cell infiltration of these tissues is common.

The significance of the prevalence of the parasite in the sebaceous glands of the nipple in this series cannot be assessed without further investigation over wider areas. It is not suggested that the presence of the parasite in the sebaceous glands of the nipple is of real importance in the pathogenesis of carcinomatous changes in the epithelium of the nipple as in Paget's disease. Its relevance as a factor in the incidence of sore nipples has been suggested.

TRACHEA, LUNGS, AND PLEURA

Langer, L., and Salvestrini, H.: *Surgical Treatment of Bronchiectasis (Tratamiento quirurgico de las bronquiectasias). Rev. med. Chile, 1946, 74: 328.*

This article constitutes a rather complete presentation of the problem of bronchiectasis, including the prognosis of the disease without surgical treatment, the clinical picture, the method of diagnosis, relative distribution of the involvement, and surgical treatment.

The preoperative preparation, stressing drainage through the bronchus and antibiotic therapy, was described. The details of the operative procedure are given at some length, and the postoperative care is also presented in detail.

A series of 104 patients were operated upon during the last 2 years, undergoing a total of 110 resections without mortality. These patients were seen on the service of Overholt in Boston, Massachusetts.

HIRAM T. LANGSTON, M.D.

Dickson, J. A., Clagett, O. T., and McDonald, J. R.: *Cystic Disease of the Lungs and Its Relationship to Bronchiectatic Cavities. J. Thorac. Surg., 1946, 15: 196.*

Twenty-two surgically treated patients with cystic disease of the lungs were selected for study. In 12 cases the cysts were developmental or congenital, in 6 cases they were acquired (including "cystic" bronchiectasis), and in 4 cases they were

indeterminate. Most of the cysts had a bronchial communication. All but 3 cysts were infected. In no case was there any evidence that bronchogenic carcinoma had its origin within the wall of one of these benign cysts.

Hemoptysis was present in 16 of the 22 cases. In cases of cystic disease of the lungs a diagnosis of pulmonary tuberculosis is often made. An accurate diagnosis of cystic disease of the lungs is largely dependent on adequate roentgenographic examination of the thorax. It is believed that bronchoscopy is of definite value, especially for the patient who is to be treated surgically, to rule out any possibility of other bronchial lesions. Occasionally, an accurate diagnosis can be arrived at only by exploratory thoracotomy. In the differential diagnosis, consideration must be given to almost all intrathoracic neoplasms, pulmonary abscesses, localized empyemas, tuberculous cavities, hydatid cysts, and diaphragmatic hernias.

The ideal treatment for cystic disease of the lungs is complete operative removal of the cystic portion of the lung with conservation of as much normal functioning lung as possible. Local excision is only occasionally feasible, as in a case in which the cyst may be attached by a narrow pedicle or loosely attached to the parenchyma of the lung. Drainage of the cyst and other supplementary operations, such as collapse procedures, usually are not satisfactory. Age appears to be no contraindication to surgical treatment.

HEART AND PERICARDIUM

Poppe, J. K., and De Oliveira, H. R.: *The Treatment of Syphilitic Aneurysms by Cellophane Wrapping. J. Thorac. Surg., 1946, 15: 186.*

The surgical treatment of aneurysms is still an open field despite the various methods mentioned in the medical literature, and even despite the modern surgical techniques available at the present time. According to Pearce, the surgical attempt at producing progressive obliteration of the lumen of the great vessels appeared in the nineteenth century.

A number of methods and devices have been advocated for the production of occlusion of large blood vessels, with unsatisfactory results in many instances. In addition to the ineffectual results and fatal complications accompanying the use of many of these methods, almost all of them, with one or two exceptions, are too traumatic for application to a dilated, thin-walled syphilitic aneurysm which is about to rupture spontaneously.

Pearce, in 1940, showed that the chronic progressive irritation, fibrosis, and foreign body reaction caused by the insertion of ordinary 300 P.T. cellophane in close proximity to the vessel, provide a method of thickening the wall and occluding the

lumen of a blood vessel without the objections mentioned.

The first recognition of the irritating properties of cellophane resulted from the studies of Page, who wrapped the kidneys of dogs in cellophane in 1939 to produce hypertension. A marked tissue reaction was said to have occurred within 3 to 5 days following the application of the cellophane. Within 2 weeks a dense fibroblastic and collagenous deposit developed over the surface of the kidney and formed a constricting hull of from 3 to 5 millimeters in thickness. This hull continued to thicken for an undetermined period of time despite the disappearance of the cellophane.

In direct contradistinction to the work of Page, Pearce, and Harrison and associates, are the results of another group who considered cellophane as a physiologically inert substance suitable for application and insertion into areas of the body in which a foreign body reaction and adhesions would be very undesirable. Donati was the first to demonstrate this inert property of cellophane, in 1946.

Later, McKeever used cellophane in the treatment of arthritis. He used type 300 P.U.T. 71 and concluded, as did Donati, that no reaction is caused by cellophane for at least two months after operation.

These various physiological reactions of cellophane exhibited diametrically opposite properties. On one hand, cellophane represented an inert substance which produced practically no foreign body reaction when left in the tissue, and, on the other hand, induced a violent fibrous tissue reaction resulting in fibrosis and contraction. This led to the conclusion that different varieties of cellophane produced entirely different physiological reactions, depending upon the chemical structure of the material. Before any satisfactory clinical application could be made of the properties of cellophane to produce a constrictive fibrosis, a distinction was needed between the physiologically inactive and reactive types of cellophane. For that reason, a series of animal experiments was conducted on dogs, in which five different basic types of cellophane were used. A very marked fibrous tissue reaction surrounding the section of the aorta in close proximity to the polythene variety of cellophane was noted in both animals in which it was used. The reaction was still acute as indicated by the cellular proliferation in the first animal in which the tissue was examined 2 weeks postoperatively. A very dense fibrous proliferation was present in the tissue surrounding the section of aorta covered with the polythene variety of cellophane in another animal sacrificed 2½ months postoperatively. In this case, not only had the wall of the aorta increased to six times its normal thickness, but the lumen of the vessel had been reduced to about one-third of its normal diameter.

A report of the successful clinical application of the polythene variety of cellophane to a fusiform aneurysm of the thoracic aorta is described in detail. The most satisfactory way to avoid the contact of the surrounding structures with this extremely re-

active polythene film seems to be to cover it with a layer of less reactive polythene, such as 300 P.U.T. 71, 300 P.T. 62, or one of the moisture-resistant varieties. Further animal experiments are being carried out at the present time on refinements in technique, this representing a preliminary report.

Polythene film was also used recently for the ligation of a recanalized ductus arteriosus in a 14-year-old colored girl with subacute bacterial endocarditis in whom the patent ductus had been ligated 4 years previously with cotton umbilical tape. A certain amount of caution is necessary, however, to keep the cellophane away from the recurrent laryngeal nerve.

The use of polythene cellophane seems to offer a successful method of gradual fibrosis and obliteration of aneurysms and large vessels. Experimental studies reported here have shown that in order to obtain the desired result, it is necessary to use a particular type of cellophane, since some varieties produce no fibrosis. Polythene cellophane has been found useful not only in the treatment of aortic aneurysms, but also in the obliteration of a patent ductus arteriosus. JOHN E. KIRKPATRICK, M.D.

ESOPHAGUS AND MEDIASTINUM

Resano, J. H.: Activities of the Department of Esophageal Diseases for the Year 1945 (Actividades del departamento de esófago durante el año 1945). *Prensa méd. argent.*, 1946, 33: 1072.

In the Argentine Republic an estimated 1,000 persons die annually from carcinoma of the esophagus. A special service for the management of esophageal lesions has been in function since the end of 1939. Five hundred and nineteen patients have been seen in this period; they presented cancer as the predominant lesion, followed by megaesophagus in the proportion of 10 or 12 cases to 1. During 1945, 21 cases with symptoms of esophageal disease were seen in which no lesion was readily demonstrable.

The total number of cases of esophageal disease seen in 1945 was 159. Of these, 121 were carcinomas, and the 21 cases already referred to were as follows: 7—megaesophagus, 4—strictures due to caustics, 3—diverticula, 2—cardiospasm, 2—simple esophageal spasm, 2—foreign body, 1—post-typhoidal esophagotracheal fistula, 1—congenital stricture, 1—dysphagia due to situs inversus, and 1—paralytic dysphagia.

The relative distribution of carcinomas in the esophagus showed 19 to be in the upper third, 36 in the middle third, and 56 in the lower third. One case involved the entire organ.

The management of these 111 cases may be summarized as follows: 5 had not been operated on at the time of the report; 33 were considered inoperable principally because of great debility, advanced age (70 years is considered an average upper limit), or uncontrollable associated diseases; 11 patients refused operation; 30 were submitted to exploratory operations; 32 underwent radical resection; 19 underwent a Torek procedure, with 11 deaths; 11

underwent resection with an intra-aortic esophagogastric anastomosis (6 deaths); and 2 underwent resection with supra-aortic esophagogastric anastomosis (2 deaths).

Resection with anastomosis is the constant aim, but is not always possible. A case of low esophagogastric lesion is reported in which the extensive neoplasm required a total gastric resection. The performance of an esophagojejunostomy was prevented by an unusually short mesentery so that a cervical esophageal stoma was made after complete extirpation of the thoracic esophagus. Feeding is maintained by jejunostomy.

HIRAM T. LANGSTON, M.D.

Resano, J. H. Notes on the Diagnosis and Treatment of Carcinoma of the Esophagus (Comentarios sobre diagnóstico y terapéutica del carcinoma del esófago). *Prensa méd. argent.*, 1946, 33: 972.

Despite the usual concept that tumors occurring in narrow portions of the digestive tract are diagnosable while still of small size, carcinoma of the esophagus comes to diagnosis relatively late. This is explained in the author's experience by:

1. The natural latent period of any disease. He estimates the length of life after the development of the neoplasm as of 2 years, for the maximum.

2. Delay on the part of the patient in seeking competent medical advice. Since the symptoms may be variable from day to day, he continues to hope that they will disappear.

3. Delay on the part of the physician in recognizing the true nature of the process while striving for relief with various antispasmodics.

In the author's experience some 20 per cent of the patients have received antitumor therapy when first seen, notwithstanding the rarity of esophageal syphilitic involvement (not 1 instance in 6,000 autopsies). One case of esophageal syphilis is briefly presented; this occurred in the author's series of more than 450 cases of esophageal disease. The stenotic areas were multiple.

Further causes for delay in treatment arise from confusion produced by the good general condition of the patient early in his symptomatic course, and the poor quality, or the improper interpretation, of the x-ray studies. Several case reports are quoted and illustrated. The accuracy of the x-ray diagnosis is attested by the statement that on the service of Finochietto, only 2 cases of carcinoma of the esophagus in a series of 350 gave normal x-ray findings.

The author calls attention to a statement attributed to Seiffert (reference omitted), in which he claims to have seen 2 cases of spontaneous cure of esophageal carcinoma. The author cites 1 personal observation in which esophagoscopy and x-ray examination revealed marked regression. This patient, however, died at the end of 16 months of an aortic perforation by the carcinoma.

The treatment is discussed at some length and illustrated. Roentgen therapy is not considered curative. Esophageal resection, with esophagogastric anastomosis, when possible, is practiced, a cervical

esophageal stoma being produced only when necessary. Eighteen successful results have been obtained: 3 with the Torek procedure, 11 with esophagogastric anastomosis below the aortic arch, and 4 with anastomosis above the arch. Two of the 3 patients who underwent the Torek procedures died at 7 and 8 months, respectively, of metastases. Five of the patients subjected to infra-aortic esophagogastric anastomosis died in from 4 to 18 months. All of the patients in whom supra-aortic anastomoses were effected have survived. The longest survival period of any patient is 26 months.

HIRAM T. LANGSTON, M.D.

Castoldi, P.: Malignant Granuloma of the Mediastinum of a Neoplastic Developmental Form with Infiltration of the Pulmonary Parenchyma (Granuloma maligno mediastinico a sviluppo neoplastiforme con infiltrazione del parenchima polmonare). *Tumori*, Milano, 1942, 28: 358.

A 16 year old girl succumbed to a huge tumor in the left side of the chest. At autopsy, 24 hours later, the mass, which was of the size of an adult head, was removed en bloc, together with the mediastinum and left lung. On histological examination the tumor proved to be typical of granuloma malignum. However, the most interesting finding was that of the left lung. This organ was collapsed, had spread over the upper, posterior surface of the granulomatous mass, and had apparently grown to it in one area.

Histological sections of the lung tissue in this area revealed, in places where the process seemed most recent, that the pulmonary alveoli were plugged with cellular elements of a marked polymorphism, in which many of the cells bore a marked resemblance to the Sternberg cells of granuloma malignum. The author characterized the whole process as one of desquamative pulmonitis. This process differed, however, from the ordinary desquamative alveolitis by the cellular polymorphism. In some of the alveoli a fine fibrillar rete was present. The alveolar septa were still present and evidenced a hyperplasia and intra-alveolar desquamation of the reticular cells.

There was no sign of a fibrinoleucocytic (exudative-inflammatory) reaction in the sense of Deak, and the author interpreted the condition as a true lymphogranulomatous pulmonitis as described by Braitenberg.

JOHN W. BRENNAN, M.D.

MISCELLANEOUS

Brock, R. G.: A Musculoplastic Incision for Posterior Thoracoplasty. *J. Thorac. Surg.*, 1946, 15: 182.

The usual incision for posterior paravertebral thoracoplasty is carried straight down through the skin and underlying muscles to the ribs, to make a J-shaped flap which is reflected forward. This method of making the incision has many disadvantages.

For the past year the author has been using a simple musculoplastic modification of this incision which seems to avoid most of its disadvantages. It is a simple and logical step and has proved very satisfactory in practice.

The usual J-shaped incision is made down to, but not through, the muscles of the back. The medial flap is now undercut as far as the midline for the whole length of the vertical limb; the undercutting is continued into the first 3 or 4 inches of that part of the incision which curves forward, typically to just beyond the anterior border of the trapezius muscle. This undercutting is carried downward and medially for some 2 inches to expose the lowest part of the trapezius to within 2 inches of its lowest origin, where it is little more than $1\frac{1}{4}$ inches wide. The most anterior part of the incision need not be undercut, but its lower edge should be retracted before the latissimus dorsi is divided. The incision in the latissimus dorsi is carried back to the lowest exposed portion of the trapezius, and this muscle is then cut through transversely to the midline. A finger is next inserted beneath the trapezius immediately next to the origin from the spinous processes, care being taken to separate the muscle from the aponeurosis covering the erector spinae mass, to which it may be moderately adherent. With scissors or a knife, the trapezius is cut as near as possible to the spinous processes and the interspinous ligaments. With the finger separating the muscle in front of it, the division is carried right up to the top of the wound. The rhomboid muscles are, of course, raised with the trapezius when they are reached, the serratus posterior superior may also be included, or left on the ribs, if desired. As the aponeurosis is being cut, a little care will enable one to see and secure the medial divisions of the posterior branches of the intercostal vessels to further minimize the blood loss. The whole muscle flap is now displaced forward in the usual way. As it is raised, the lateral division of the posterior branches of the intercostal vessels

is displayed and the muscles can be secured and divided without blood loss. If the serratus posterosuperior muscle has been lifted with the flap, it can now be separated from its insertion into the ribs. At the end of the operation the reflected muscle layer is sewed back to its original attachment to the spinous process and the supraspinous and interspinous ligaments.

At the second stage the maneuver is repeated; the separation is made with ease and there is very little "gumming" together of the layers as is seen when the muscles have been cut through. The aponeurosis can be cut from the midline as easily as at the first stage and can be resutured into position just as easily and securely. The separation of the muscle flap is almost entirely bloodless at the second stage.

The advantages claimed for this musculoplastic incision are as follows:

1. A long, unsurgical division of muscle tissue is avoided, with consequent diminution of the blood loss, interruption of the nerve supply, and subsequent impairment of the function from atrophy and fibrosis.
2. The posterior scapular artery is completely out of danger when the highest part of the incision is made.
3. The exposure is definitely improved, the access to the posterior ends of the ribs is simplified, and it is not necessary to carry the incision quite so high as when the muscles are cut through and not reflected.
4. The two suture lines are not superimposed, and if the skin sutures should give way, the extrafascial space is protected by the muscle layer.
5. There is virtually no bleeding from the muscle layer at the second stage.

JOHN E. KIRKPATRICK, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Salsano, D.: *Fibroma of the Left Rectus Abdominis Muscle in the Male* (Fibroma del muscolo retto addominale di sinistra in uomo). *Ann. ital. chir.*, 1943, 22: 572.

The primitive fibroma of the abdominal wall, especially in the male, is extremely rare. Indeed some authors deny its entity and attribute tumors described as such in males to the fibromatous products of chronic inflammations or to the reparative processes following rupture of a muscle. The author reports a case of tumor situated in the left upper abdominal wall in which there could be no doubt, either from the clinical history or from the histological findings, of its being a fibroma.

The robust soldier whose case is reported had accidentally noted a small tumefaction of the left superior quadrant of the abdominal wall about a month previously. At operation a walnut sized mass was exposed under the anterior sheath of the left abdominis rectus muscle about 2 finger-breadths from the midline and the same distance above the level of the umbilicus. The growth was situated at the level of one of the tendinous inscriptions of the abdominis rectus but had developed within the entire thickness of the muscle and showed no evidence of capsule formation.

The new growth was excised, the incisions reaching well into the healthy muscle, and the histological examination reported the findings of a simple fibroma. There was an intermixture of some striped muscle fibers showing the simple degenerative picture of pressure from the surrounding fibrous tissues. At the edge of the tumor mass its fibers seemed to be continuous with the fibers of the intermuscular connective tissues.

Seven months later the patient was perfectly well and there was no evidence of local recurrence or of metastasis.

JOHN W. BRENNAN, M.D.

GASTROINTESTINAL TRACT

Duran-Jorda, F.: *A Microincineration Study of the Flat Epithelial Layer Covering the Alimentary Tract*. *Brit. J. Surg.*, 1946, 33: 346.

The author has demonstrated, by using the microincineration technique, the organic nature of the flat epithelial layer, previously described by him, which covers the gastric and intestinal mucosae and the gall bladder mucosa.

The gastric and intestinal mucosae are covered by a layer of flat epithelial cells which contains a variable number of diapedic cells and a network of capillaries. Between the layer and the pits of the glands there is a kind of albuminous fluid which in some stomachs becomes clotted and produces a cast of the whole elements contained in the flat epithelial

layer. This layer is very friable, especially because it is bathed in the juices contained in the gastric and intestinal mucosae. The link between the layer and these mucous membranes is very fragile, and it was for this reason that the author was compelled to develop a new method of fixation to study the layer. This method will be referred to herein as formalin vapor fixation, and was carried out by submitting the tissues to formalin vapor in a closed atmosphere, at room temperature, for 2 or 3 days.

As a consequence of uncertain methods of staining both the cytoplasmic cellular mucus and the supposed mucus covering the mucous membrane, the author decided to resort to a more drastic method of investigation. After a careful consideration of the problem he concluded that the most satisfactory technique to reveal the organic nature of the flat epithelial layer described was to submit the tissues to microincineration for then a subsequent study of the remaining ashes could be made.

Mucin cannot leave any mineral ashes after incineration. This is a fact well known by research workers who have used the microincineration method of studying the ashes contained in the tissues. As the mucin does not leave any ashes after its incineration, the spaces occupied in the cytoplasm of the cells secreting mucin or pseudomucin are empty when the tissue is studied after incineration. When describing the cells in the mucous membrane of the stomach, small intestine, and colon, microincinerists are quite definite that the empty spaces seen in the cytoplasm of some mucous membrane cells are the places previously occupied by the mucus, which does not leave any ashes. Then it can be concluded that if the layer covering the gastric and intestinal mucosae is basically formed by an accumulation of mucinous material, it will disappear after incineration and be substituted by an empty space.

To carry out these studies alternate slides of serial sections of the mucosae to be investigated were subjected to microincineration. From these sections, the first was stained with hemalum and eosin, the second was submitted to microincineration, and the third was treated with a mucin stain. The specimens selected had previously been subjected to formalin vapor fixation and embedded in paraffin blocks. Occasionally, one of the stained slides was incinerated after some photomicrographs were made of it, and after microincineration more photographs were taken of the same fields to compare the two sets. The specimens of different mucosae studied came from surgical specimens, as the protective layer is destroyed immediately after death, and the author supplemented the investigations by making a further study of some specimens from the mammal alimentary tract. The animals used were rabbits.

In the stomach there is a layer which comes from the upper layer of the tunica muscosa of the esophagus, covers all of the stomach, and passes to the intestine. This layer has been seen to cover not only the surface of the stomach, but also some of the pits of the glands. Sometimes, in the same section, it can be observed how some portions are formed only by single cells, while others are formed by multiple cells. This layer is rich in a network of capillaries. After microincineration, the layer leaves thick ashes. The layer covering the stomach is thicker than the layer in the small intestine; the explanation for this could be the presence of hydrochloric acid in the gastric mucosa. The layer can be peeled off from the stomach if the mucous membrane has been subjected to formalin vapor fixation. It is very transparent and can be sectioned. The incineration of the layer itself leaves ashes, which demonstrates that the layer is not merely dried, inspissated mucus.

In the small intestine there can also be found a covering layer, this is confirmed by incineration. The layer appears to be very thin and contains small capillaries. The thinness of the layer can probably be attributed to the fact that in the intestine the pH of the media is in the alkaline range.

In the appendix the covering layer shows diverse cellular contents and in some microscopical fields it is monoecellular. In other fields it contains a very large quantity of diapedesic cells. The existence of capillaries can also be demonstrated in this layer covering the appendix. After microincineration the ashes are very thick, which is in accordance with the number of cells contained in the covering layer. The explanation for these thick ashes is quite logical when one considers that the nuclear chromatin of the diapedesic cells is pyknotic and concentrated.

In this organ the layer has the same appearance as the layer found in the stomach. It is very thick and vascularized, probably because a great deal of bacterial fermentation takes place in the colon as a result of the anabolism of the hydrocarbonates present in the food remnants, and consequently the mucosa required a thick layer as a protection against the organic acids formed by bacterial and enzymatic fermentation. The ashes of this layer are also very thick, similar to those of the layer in the gastric mucosa.

By observing the layer from the colon mucosa to the rectum and the anal stratified squamous epithelium, it can be seen how the layer passes from one organ to another and later becomes included in the stratum lucidum of the anal skin. In some of the specimens it is evident that the covering layer still contains capillaries, which are continued in the stratum lucidum of the anal skin, and this raises the question as to whether there are capillaries between the layers of the stratum lucidum and the stratum corneum in the skin.

The layer in the gall bladder appears to be similar to that found in the small intestine, and contains a few cells and small capillaries. After incineration it leaves well marked ashes.

After submitting different specimens of mucous membrane from the alimentary tract to the process of microincineration the author is now in a position to dismiss definitely the supposition that the existence of this layer is unreal, or is the consequence of the clotting of mucus present in the gastric and intestinal tract as a result of the formalin vapor fixation for the preparation of these organs. There can, therefore, be no doubt that the covering layer, which is formed by flat epithelial cells, diapedesic cells, and capillaries, is a true organic formation, which should be considered in the future study and description of the histology and pathology of the mucous membrane of the stomach, intestines, and gall bladder.

CHARLES BARON, M.D.

Ladd, W. E., Ware, P. F., and Pickett, L. K.: Hypertrophic Pyloric Stenosis. *J. Am. M. Ass.*, 1946, 131: 647.

The senior author and his associates are noted for many valuable contributions to the management of congenital hypertrophic pyloric stenosis. This report is a general review of the subject and deals particularly with 380 patients operated on between 1930 and 1945.

Eighty-five per cent of the patients with hypertrophic pyloric stenosis are males and frequently they are the first born of a family. The pathogenesis probably results from a combination of pylorospasm and work hypertrophy due to a congenital pyloric tumor together with edema of the mucous membrane from mechanical irritation by curds. The essential pathological finding is hypertrophy and hyperplasia of the circular smooth muscle layer of the pylorus.

The onset of symptoms occurs between the second and fifth weeks of life. Dehydration is usually pronounced when the patient is first seen. Vomiting begins as infrequent regurgitation but progresses to an explosive nature and soon occurs after almost every meal. However, the child remains hungry and will feed eagerly even immediately after vomiting. The vomitus never contains bile. The child soon loses weight, the stools become scanty, and alkalosis develops.

The most important physical finding is a palpable olive sized mass in the right upper quadrant of the abdomen. This can be identified best immediately after the infant has vomited. Peristaltic waves may be observed during feeding and, characteristically, appear only in the epigastrium.

Differential diagnosis is seldom difficult. One must consider pylorospasm, infectious vomiting, improper feeding, intracranial injury, achalasia, and extrinsic and intrinsic intestinal obstruction.

The most important aspect of preoperative care is proper fluid therapy. It is essential to restore the baby to as nearly a normal nutritional state as possible by correction of dehydration, ketosis, and chloride deficiency. Operation is never an emergency procedure; 2 or 3 days of preparation should be the minimum. In general, the infant should receive

from 2½ to 3 oz. of fluid per pound of weight daily. In poor risk debilitated patients plasma and whole blood transfusions will be necessary to restore the normal serum protein level and to improve the patient's general condition. These may be given in amounts corresponding to 10 c.c. per pound of body weight. Vitamin C may be given in the dlysis fluid. Full formula feedings are maintained during the preoperative period regardless of the vomiting, for small amounts of feeding will be absorbed.

In the preparation for operation conservation of body heat is of great importance. A small urethral catheter serves to keep the stomach aspirated during operation. Ether given by open drop is the anesthetic of choice. The Robertson gridiron incision has been the preferred surgical approach to the lesion in this group of patients.

The operative procedure of pyloromyotomy is described in detail, and a satisfactory postoperative feeding regimen is given.

Complications include duodenal perforation, otitis media and pneumonia, wound infection, and evisceration.

In this series 380 patients with hypertrophic pyloric stenosis were operated on with 4 deaths. In the past 3½ years there have been no deaths among 225 consecutive cases. EDWARD W. GIBBS, M.D.

Barber, M., and Franklin, R. H.: Bacteriology of Peptic Ulcer and Gastric Carcinoma. *Brit. M. J.*, 1946, 1: 951.

Unexplained sepsis, which occasionally occurs after apparently uncomplicated cases of partial gastrectomy, may lead to the development of a subdiaphragmatic abscess or, more rarely, to general peritonitis and death. The present investigation was undertaken to determine whether any pathogenic bacteria were present in the stomach and duodenum at the time of operation.

The normal bacterial flora of the alimentary tract has been the subject of much work and even more discussion. Another aspect which has caused considerable controversy is the importance of bacteria in the alimentary tract. The possible activities of bacteria in the intestines under different conditions are legion and remain a matter for speculation.

In contrast to the prolific flora of the large intestine, the stomach and first part of the duodenum in the healthy adult are usually sterile, except just after a meal. Spallanzani (1783) was the first to draw attention to the antiseptic properties of gastric juice. Garrod (1939) showed that susceptibility to the bactericidal action of hydrochloric acid of any pathogenic bacteria entering the body via the alimentary tract varied considerably, and that gastric juice was more bactericidal than hydrochloric acid of equivalent strength. In gastric disease it has repeatedly been shown that bacteria may actually multiply in the stomach.

More recent work on the bacteriology of the stomach and duodenum has been carried out mainly to answer two questions: (1) whether infection plays

a part in the causation of peptic ulcers; and (2) whether postoperative sepsis is related to the bacteria which are present in the stomach at the time of operation.

In spite of a voluminous literature the number of studies in which organisms were taken direct from the stomach and duodenum at operation and the isolated bacteria were fully identified is small.

In the present study, swabs were taken from the mucosa of the stomach and duodenum at operation in a series of 50 patients undergoing partial gastrectomy. Each swab was inoculated on to two blood-agar plates, one of which was then cultivated aerobically and the other anaerobically. Bacteria appearing on these plates were isolated in pure culture and, when possible, identified. In most cases test meals were given before operation and a portion of ulcer was examined histologically. Bacteria were isolated from 16 of 40 cases of benign ulcer and 9 of 10 cases of carcinoma. Pyogenic cocci (*Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Lancefield A hemolytic streptococci*) were isolated from 7 cases.

Monilia albicans, nonhemolytic streptococci, and coliform bacilli were isolated from many patients who had a normal or high gastric acidity. All other bacteria were isolated only from cases in which the test meal showed a condition approaching achlorhydria. In this series of 50 cases septic postoperative complications were no higher among the 25 cases with positive cultures than among the other 25. The isolation, however, of such organisms as *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Lancefield A hemolytic streptococci* makes it clear that bacteria in the stomach at the time of operation are a potential source of infection, and preoperative medication might be advisable at least in the cases with low gastric acidity.

JOHN E. KIRKPATRICK, M.D.

Debeyre and Jouve: Ulcer of the Greater Curvature of the Stomach Penetrating into the Spleen with Secondary Perforation into the Peritoneal Cavity (Ulçère de la grande courbure de l'estomac tétrébrant dans la rate secondairement perforé en péritoine libre). *Presse méd.*, 1946, 51: 395.

The authors report a case of ulcer of the greater curvature of the stomach with penetration into the spleen and secondary perforation into the free peritoneal cavity. The patient was a 69 year old man with symptoms of an acute perforation of 2 days' duration. He was treated by immediate operation, with resection of the ulcer without splenectomy, and died 48 hours after operation.

A review of the literature failed to disclose an identical case, but the authors collected 19 reports of perforated ulcer of the greater curvature of the stomach. In 8 of these the lesion had penetrated into the spleen, and in 5 there was penetration into adjacent viscera. Five patients had a perforation into the free peritoneal cavity, and 2 had perforation into the lesser peritoneal cavity.

In general, penetrating and perforating ulcers in the greater curvature have a less favorable prognosis than similar lesions located elsewhere in the stomach. The reported mortality rate is 20 per cent.

EDWARD W. GIBBS, M.D.

Gordon-Taylor, G.: The Present Position of Surgery in the Treatment of Bleeding Peptic Ulcer. *Brit. J. Surg.*, 1946, 33: 336.

The results of therapy during recent years in more than 1,700 cases of hemorrhaging peptic ulcer treated at the St. George's and the Westminster Hospitals, London, St. Mary's Hospital, Balham, certain hospitals of the London County Council and the Westminster County Council, and of the larger, unspecified, Royal Naval Hospitals in the United Kingdom are collated and discussed. Cases of bleeding peptic ulcer treated nonoperatively are considered particularly in a conjecture as to the percentage of patients that might have been saved had surgery been performed.

Gordon-Taylor notes that the mortality of these cases has decreased in the past 20 years because of more adequate medical management, especially the early institution of "drip transfusion." The mortality is now from 10 to 11 per cent as compared with 24 per cent for the period from 1926 to 1933 despite the fact that many patients have been aged and infirm. The author believes that every case of hematemesis or melena should be transfused early with whole blood at 40 drops per minute. Early operation (before Finster's critical third day) gives a definitely lower mortality rate, hence close consultation between physician and surgeon is required. When surgery is performed it should be directed only at control of the bleeding; it must be quick and gentle, and abdominal exploration is discouraged. In cases in which it appears obvious from the terrific bleeding that a larger vessel has been eroded immediate intervention is indicated. Urgent operation is indicated in those cases of hemorrhage in which there is also evidence of obstruction because in these bleeding is most apt to persist or to recur promptly. Urgent surgery is indicated in persons past the age of 50, particularly if the radial artery is thickened and tortuous, and is similarly indicated in these older patients if the pain persists after hemorrhage. Recurrent hemorrhage in a patient under what should be adequate medical control is deemed an indication for surgical intervention. The foregoing views are supported by Avery Jones who observes that one-half of the patients over 50 years of age died after one recurrent hemorrhage, and 60 per cent after a second bleeding.

Lest his reader misapprehend that he is recklessly in favor of surgery in bleeding peptic ulcer patients, Gordon-Taylor states: "Every case must be considered on its own merits; there can be no hard and fast rules. Antecedent disease and intercurrent illness, the previous habits of the patient, his physical conformation, and all that constitutes a 'good or bad surgical risk' must be weighed carefully."

Partial gastrectomy has been the usual operation of choice, but no one technique is applicable to all cases. The snail-like closure of the duodenal stump which forms a tampon to a penetrating duodenal ulcer, as devised by Judin, is described in detail.

That the mortality in cases operated upon before the third day is far lower than that in cases operated upon after the sixth day is not a contraindication to late surgery. There have been many dramatic successes in cases thought to be hopeless. The author recalls understandingly the gloomy attitude of the Moscow surgeon, Judin, who for the thirtieth, fortieth, and even the fiftieth time in the postmortem room observed the erosion of an artery in an ulcer crater quite accessible to surgery.

WAYNE CAMERON, M.D.

Chesterman, J. T.: Neurogenic Ileus. *Brit. M. J.*, 1946, 1: 830.

This article is a consideration of ileus due to neuromuscular imbalance, or neurogenic ileus. The problems of neurogenic ileus are discussed under three main headings: (1) intestinal movements and conduction, and their alterations in neurogenic ileus; (2) the sites of action of stimuli producing such alterations; and (3) the factors giving rise to such stimuli in clinical practice.

The gradients theory of polarity proposed by Alvarez to account for phenomena of intestinal motility provides a physiological basis for certain alterations in the neuromuscular balance of the intestine. Various factors may alter the different gradients of the intestine, and these alterations may affect the whole or part of the intestine. There is no reason to doubt that nervous stimuli reaching the bowel may produce such alterations. Alvarez has shown that any stimulation which raises the tonus, activity, or irritability of a segment of the bowel tends to slow the progress of waves and material approaching this segment on the oral side and to hurry the progress of material leaving it on the caudal side. The author believes that experimental and clinical evidence shows the converse to be equally true: that any stimulation which flattens or reverses the gradients of a segment of bowel tends to increase the activity of the segment on the oral side and depress it on the caudal side for a variable distance. This concept he terms the "flattened gradients theory of neurogenic ileus." The local or general flattening of intestinal gradients, with its alterations in the motor function of the bowel, gives a satisfactory explanation of the mechanism of neurogenic ileus. This theory infers that the type of ileus, spastic or distensive, the extent in length of the bowel involved, and the length of time the bowel remains in ileus are due to the stimulus and the condition of the bowel at the time of reception of the stimuli.

Experimental studies were carried out to determine the levels in the neuromuscular mechanism at which ileus may arise. Confirmation was obtained of the value of spinal analgesia in the release of neurogenic ileus which had been produced by iodine

irritation of the peritoneal surface of an area of bowel in anesthetized dogs. The next step was the attempt to induce neurogenic ileus in a dog while under spinal analgesia. It was found that the injection of several milliliters of methylated spirit between the leaves of the mesentery near the bowel margin produced a localized ileus in which the affected bowel distended and became filled with gas and led to a damming back of the intestinal contents on the oral side for varying periods up to several hours. In no case could the effect be attributed to any alteration in the vascular supply of the area. In cats the same procedure carried out under intraperitoneal nembutal analgesia also leads to neurogenic ileus, but in young animals it is often of a spastic rather than of a distensive type. These results have been confirmed in man. These observations lend support to the flattened-gradients theory of neurogenic ileus and also make it reasonable to suppose that so-called sympathetic inhibition of motor activity is not its only cause, but that ileus can arise from stimuli affecting the muscular or nervous mechanism of the bowel.

The factors giving rise to neurogenic ileus in clinical practice are: traumatic, infective, toxemic, and idiopathic.

JOHN L. LINQVIST, M.D.

Adams, R., and Miller, W. H.: The Surgical Treatment of Intestinal Tuberculosis. *Surg. Clin. N. America*, 1946, 26: 656.

Among a series of 19 surgically treated cases of intestinal tuberculosis, closure of an abdominal fistula was done in 4 cases with recurrence in 3.

Resection of the right colon with the formation of a Mikulicz ileotransverse colostomy and secondary closure was done in 7 cases. Four patients remained well from 9 months to 3½ years later; 1 patient with coexisting carcinoma of the cecum died 2½ years later of carcinomatosis; 1 in whom the intestinal tuberculosis was eliminated revealed progression of the pulmonary disease; and the last patient died 4 years after operation with recurrence.

Resection of the right colon with primary ileocolic anastomosis was done in 3 cases. There was 1 post-operative death. Two patients were well 3 months and 8 months after operation, respectively.

Resection of involved segments of the small intestine with primary side-to-side anastomosis was accomplished in 2 cases and resulted in recession of the symptoms for a year.

Two side-tracking ileotransverse colostomies were done. One patient died 12 days after operation and 1 survived 9 months.

Resection of the sigmoid and a painful associated abscess, with establishment of a permanent colostomy, was accomplished in 1 case. The pain was relieved but perineal drainage has persisted for 2 years.

The authors conclude that tuberculous fistulas rarely can be successfully closed in the presence of active intestinal tuberculosis. A diversional colostomy should be maintained until the tuberculous process has remained quiescent for at least a year. When there is difficulty in determining the extent of

involvement in the right colon, an ileotransverse colostomy of the Mikulicz type with secondary closure is less hazardous than a primary anastomosis.

Any coexisting active pulmonary lesion should be arrested before an abdominal operation for intestinal tuberculosis is attempted for patients with acute obstruction, internal perforation, or carcinoma.

EDWARD W. GIBBS, M.D.

Baker, H. L., and Halley, H.: Neurofibroma of the Small Intestine with Massive Hemorrhage. *Ann. Surg.*, 1946, 123: 1067.

Benign tumors of the small intestine are comparatively rare. The most common are lipomas, adenomas, hemangiomas, pancreatic rests, cysts, and fibromas. Of these, the fibroma is the rarest.

Two cases of neurofibroma of the small intestine are reported. They were pedunculated in type, and caused very severe intestinal hemorrhage.

The prefix "neuro" used in the term neurofibroma implies a special origin to what is otherwise an essentially fibrous type of neoplasm. The cell concerned is either from the sheath cell about a nerve fiber, or the fibroblast of the delicate framework of connective tissue supporting the nerve fibers. The cells composing these neurofibromas appear and act more like fibroblasts, their presence being associated with the production of fibrils of reticulum and relatively smooth muscle cells, not only individually but in bundles. Therefore, there is a group of similar neoplasms of three different types: the fibroma, arising from the ordinary fibroblasts; the neurofibroma, arising from a special fibroblastlike cell associated with nerve fibers; and the leiomyoma and leiomyosarcoma, arising from smooth muscle cells alone or together with the ordinary fibroblasts.

The demonstration of the point of origin of any particular tumor, as in the 2 cases reported, is often impossible, because of alterations resulting from the growth and size of the tumor when it makes itself clinically apparent. Grossly, a neurofibroma in the small intestine is an encapsulated tumor of variable size and slow in growth, which will produce symptoms which depend on the level at which it occurs, the degree to which it extends into the lumen, and its susceptibility to hemorrhage.

Since benign tumors have been observed most frequently in the ileum and duodenum, these portions of the small intestine should be first examined when an exploratory celiotomy is done. The tumor of the small intestine, so as to be either antimesenteric or to extend into the mesentery. If the tumor is pedunculated, there is a predisposition to intussusception with acute obstruction in a patient previously free of benign tumor. The existence of a pedicle allows ready removal of the tumor, and, of course, however, may result in spontaneous amputation. The possibility of obstructive processes in some

The tendency toward bleeding, often pronounced in benign tumors of the duodenum, is associated with the vascularity of the mucosa and of the tumor, with changes in the lining, such as pressure atrophy or ulceration, or with ischemic necrosis of the tumor. Predisposition to hemorrhage occurs with the disseminated focal necrosis incident to scattered thrombi in the small vessels.

Exclusive of other factors, the prognosis is favorable. In the literature examined, no recurrences have been reported. In patients with severe intestinal hemorrhage, especially when bright red blood appears in the stool, and in whom the etiological factor is doubtful, the possibility of the existence of a benign tumor of the small intestine should be considered, and a search made for its presence.

SAMUEL KAHN, M.D.

Lahey, F. H.: A Discussion of the Modified Mikulicz Operation for Carcinoma of the Colon and Its Technique. *Surg. Clin. N. America*, 1946, 26: 610.

The author describes his modification of the Mikulicz operation, which is as radical as, if not more radical than, the most primary resections with anastomosis. The method presents no limitations as to the extent of colon or mesentery which can be removed and is applicable to any segment of the colon down to the lower sigmoid. It is possible to decompress the bowel as soon as the operation is completed. In the author's hands the operability rate has been 83 per cent and mortality 2.7 per cent.

The author has employed his procedure in cases of ulcerative colitis (segmental in character), regional ileitis, polyposis, and carcinoma of the colon. The method offers the opportunity to examine the remaining loops of the bowel with the endoscope for the possibility of adjacent polyps.

A palliative resection forms a contraindication to the author's method because the latter complicates and makes less satisfactory the limited period of time available to the patient. For that reason, in this type of palliative operation he has always employed anastomosis of the ileum to that portion of the colon beyond its resected segment.

The Mikulicz operation is especially valuable in patients with fat mesenteries, with fatty epiploic appendages, or with diverticula, in whom an accurate end-to-end anastomosis of the colon is difficult.

The operation is done through either a right or left rectus incision and never through the McBurney or midline incision.

If great difficulty would be encountered in peritonealizing the right gutter region of the hepatic flexure, no attempt is made to do this.

When the lesion is in the lower loop of the sigmoid where an inadequate amount of bowel tube remains below for the application of the modified Mikulicz procedure, the abdominosacral type of operation rather than any type of resection with pelvic anastomosis is to be preferred.

The second stage closure of the Mikulicz operation has been 100 per cent successful as far as persistent

fistulas are concerned. A minimum time of 2 months should elapse before the second stage closure of the enterostomy is attempted.

JOSEPH K. NARAT, M.D.

Sugarbaker, E. D.: Coincident Removal of Additional Structures in Resections for Carcinoma of the Colon and Rectum. *Ann. Surg.*, 1946, 123: 1036.

As a result of the tendency toward increasing radicalism in dealing with carcinomas of the large bowel, more frequent attempts are being made to remove tumors which have definitely invaded the adjacent structures, or are suspected of doing so.

Forty-two such cases are presented, in which additional organs were removed in order to accomplish the removal of a rectal or colonic cancer. The poorer general condition of these patients as well as the increased extent of the operations is reflected in an appreciably higher operative mortality.

Justification for such procedures is found in the fact that 19 of 34 patients who survived the operation are still living after considerable periods of time.

SAMUEL KAHN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Beavan, T. E. D., and Duncan, G. W.: Congenital Atresia of the Common Bile Duct. *Brit. J. Surg.*, 1946, 33: 378.

The case of a 5 weeks old child with congenital atresia of the common bile duct is described. Cholecystogastrostomy was performed with a successful outcome. This was the ninth successful case reported in the literature, and apparently the first in England.

In this case the differential diagnosis was not difficult. It was important to exclude icterus gravis neonatorum. The late onset of the jaundice, together with the fact that the mother and child were both rhesus-positive, and the absence of an erythroblastic picture in the blood film, ruled out icterus gravis neonatorum, the most important alternative. The presence of obstructive jaundice would not be conclusive evidence against this diagnosis, because in certain of the more severe cases of this disease, the blood destruction is so great that an obstructive jaundice is caused by the blocking of the bile ducts. Anemia may occur as a secondary manifestation in any infection; therefore it is not a helpful diagnostic feature. Congenital syphilis would only exceptionally give rise to a severe jaundice; a mild degree of jaundice, coupled with hemorrhages, a rash, enlarged liver and spleen, and roentgenological changes in the long bones, would be expected. Acholic jaundice rarely gives rise to severe jaundice of the obstructive type at such an early age; a mild jaundice with anemia and increased fragility and microspherocytosis are more commonly found. Physiological icterus does not really enter into the question as it clears up early and is not severe. Jaundice due

to sepsis is uncommon, and the severe constitutional disturbance and the presence of bile in the stools would exclude it. Infective hepatitis has not been reported in so young an infant. The long incubation period would at least make it unlikely to occur before the child was from 4 to 6 weeks old, unless the mother was also infected and then she would also become jaundiced. The Van den Bergh test would be biphasic. Obstruction by a mucus plug can only be diagnosed at operation, as it presents the same clinical picture.

CHARLES BARON, M.D.

Aldis, A. S.: Injuries to the Pancreas and Their Surgical Treatment. *Brit. J. Surg.*, 1946, 33: 323.

Injuries to the pancreas are uncommon. Most injuries of the pancreas are associated with extensive injuries to other abdominal viscera, the liver, spleen, and stomach being most commonly involved, and thus they are often beyond the reach of surgical aid. However, the close apposition of the body of the pancreas to the unyielding body of the first lumbar vertebra makes it possible for the pancreas to be crushed, ruptured, or torn across in crush injuries of the upper abdomen, and especially if the trauma is a very sudden one which produces its effects before the abdominal musculature has had time to guard against the blow. In such cases the pancreas may be injured apart from any other viscus. The trauma which may give rise to injuries may be surprisingly slight and is often not sufficient to produce any wounding or bruising of the parietes. This is probably a reflection of the flaccid condition of the abdominal musculature at the time of the accident, which in itself made the injury possible. Such an injury may vary from complete rupture of the gland to simple bruising, and naturally the condition of the patient will vary accordingly. In the severe injuries with complete rupture there will be no doubt in the mind of the surgeon that laparotomy will be required, although no exact preoperative diagnosis can be made. In this connection attention may be drawn to the importance of shoulder-tip pain on the left side in injuries to the pancreas which produce effusions into the lesser sac.

Trauma may produce late results in the form of a cyst or pseudocyst of the pancreas. In all the reported series, cysts following inflammatory conditions of the pancreas are very much commoner in women than in men, being commonly associated with chronic cholecystitis and cholelithiasis; but those resulting from trauma occur more commonly in males, in association with the greater hazards of their occupations.

All 3 of the cases reported in the present article were in males. The time interval between the infliction of the trauma and the appearance of the cyst is quite variable, from a few days to more than a year, but many cysts seem to develop within a month or 6 weeks of the injury, and this period of time may be taken as typical. The pathological processes which lead to the formation of a cyst in such typical cases would appear to be as follows:

Bruising of the pancreas produces a hematoma beneath the capsule into which the damaged pancreatic cells release their ferments. Fat necrosis is often seen in immediate operations upon pancreatic injuries. The trypsin in the juice, while normally inactive as secreted, becomes activated by contact with damaged and devitalized tissues and digests the clot, thus giving rise to further bleeding from the thin walled pancreatic vessels. This process is repeated and the cyst enlarges as a result of repeated hemorrhages. The digestion may go on until the pancreatic duct is involved, when the size of the cyst will be rapidly increased by the admixture of pancreatic juice.

No doubt there are many variations of this process and the cysts of rapid onset are probably due to rupture of the capsule of the pancreas, frank hemorrhage, and escape of pancreatic fluid into the lesser sac of the peritoneum. The characteristic swelling in the left hypochondrium may be easily seen as well as felt. Pancreatic cysts may extend in various directions, above the stomach, between the stomach and the colon, or downward behind the colon into the pelvis, but by far the most common are those between the stomach and colon, which produce the classical appearance of swelling in the epigastrium or left hypochondrium.

Of the accessory methods for confirming the clinical diagnosis, the most consistently valuable is the barium meal roentgenographic examination, which will show a variety of deformations of the stomach or duodenum produced by the pressure of the large extragastric mass.

Surgery holds out 3 possible and satisfactory forms of treatment for cysts of the pancreas. The three types of operation which have been advocated and applied are excision, marsupialization and drainage, and primary anastomosis between the cyst and the stomach or small intestine. Of the first it may be said that, while the most radical, it is seldom practicable for technical reasons. The second method has stood the test of time and experience and probably represents the standard procedure at the present day. It has the merits of being easy and of universal application, and in fully 80 per cent of cases it produces a rapid cure of the condition. On the other hand, however, recurrences are by no means unknown, and in some cases in which there is major damage to the pancreatic duct or ducts the drainage of the cyst may be followed by the development of a troublesome and intractable pancreatic fistula, although in most cases the fistula will close spontaneously in course of time. The third method is of more recent origin and has been introduced with a view to overcoming the objections which have been advanced to the method of treatment by marsupialization and drainage. It does not yet have the weight of experience behind it that marsupialization and drainage have, but so far as it has been tried it is probably the most satisfactory treatment that we have to date. Of the 7 cases reported in this article 5 were treated by marsupialization, 1 by evacuation

INTERNATIONAL ABSTRACTS OF SURGERY

The tendency toward bleeding, often pronounced in benign tumors of the duodenum, is associated with the vascularity of the mucosa and of the tumor, or ulceration, or with ischemic necrosis of the tumor. Predisposition to hemorrhage occurs with the seminated focal necrosis incident to the thrombi in the small vessels.

Exclusive of other factors, the prognosis is favorable. In the literature examined, no recurrences have been reported. In patients with severe intestinal hemorrhage, especially when bright red blood appears in the stool, and in whom the etiological factor is doubtful, the possibility of the existence of a benign tumor of the small intestine should be considered, and a search made for its presence.

SAMUEL KADIN, M.D.

Lahey, F. H.: A Discussion of the Modified Mikulicz Operation for Carcinoma of the Colon and Its Technique. *Surg. Clin. N. America*, 1946, 26: 610.

The author describes his modification of the Mikulicz operation, which is as radical as, if not more radical than, the most primary resections with anastomosis. The method presents no limitations as to the extent of colon or mesentery which can be removed and is applicable to any segment of the colon down to the lower sigmoid. It is possible to decompress the bowel as soon as the operation is completed. In the author's hands the operability rate has been 83 per cent and mortality 2.7 per cent. The author has employed his procedure in cases of ulcerative colitis (segmental in character), regional ileitis, polyposis, and carcinoma of the colon. The method offers the opportunity to examine the remaining loops of the bowel with the endoscope for the possibility of adjacent polyps.

A palliative resection forms a contraindication to the author's method because the latter complicates and makes less satisfactory the limited period of time available to the patient. For that reason, in this type of palliative operation he has always employed anastomosis of the ileum to that portion of the colon beyond its resected segment.

The Mikulicz operation is especially valuable in patients with fat mesenteries, with fatty epiploic appendages, or with diverticula, in whom an accurate end-to-end anastomosis of the colon is difficult.

The operation is done through either a right or left rectus incision and never through the McBurney or midline incision.

If great difficulty would be encountered in peritonealizing the right gutter region of the hepatic flexure, no attempt is made to do this.

When the lesion is in the lower loop of the sigmoid where an inadequate amount of bowel tube remains below for the application of the modified Mikulicz procedure, the abdominosacral type of operation rather than any type of resection with pelvic anastomosis is to be preferred.

The second stage closure of the Mikulicz operation has been 100 per cent successful as far as persistent

fistulas are concerned. A minimum should elapse before the second stenterostomy is attempted.

JOSEPH

Sugarbaker, E. D.: Coincident Functional Structures in Resection of the Colon and Rectum. 193: 1036.

As a result of the tendency to radicalism in dealing with carcinoma of the bowel, more frequent attempts are made to remove tumors which have definite adjacent structures, or are suspected to be adjacent to them. Forty-two such cases are presented in which the removal of a rectal or colonic carcinoma was associated with the removal of a functional organ. The general condition of these patients was such that the extent of the operations was appreciably higher operative mortality for such procedure: fact that 19 of 34 patients who survive are still living after considerable time.

Bevan, T. E. D., and Duncan, G.: Atresia of the Common Bile Duct. 1946, 33: 378.

The case of a 5 weeks old child with atresia of the common bile duct is described. Cystogastrostomy was performed with outcome. This was the ninth successful case reported in the literature, and appeared in England.

In this case the differential diagnosis was difficult. It was important to exclude neonatorum. The late onset of jaundice, together with the fact that the mother's blood picture in the blood film, ruled out a blastic picture in the blood film, ruled out a gravis neonatorum, the most important presence of obstructive jaundice in the blood destruction is so great that an anemia is caused by the blocking of the blood. Any infection; therefore it is not a helpful feature. Congenital syphilis would not usually give rise to a severe jaundice; a mild jaundice, coupled with hemorrhages, a large liver and spleen, and roentgenological jaundice rarely gives rise to severe jaundice. A ductive type at such an early age; a mild anemia and increased fragility and logical icterus does not really enter into the picture as it clears up early and is not severe. Jaundice

discussed under the headings: (1) diet, (2) drugs, and (3) other measures. Since the volume of the secretion is largely governed by the secretin mechanism, which is in turn dependent upon the motility of the stomach and the acidity of its contents, any measures which will lessen these might be expected to bring about a reduction in the volume of secretion.

Wohlgemuth instituted his dietary regimen for pancreatic fistulas and this has remained the standard since his day. His method was briefly to give a high fat, low carbohydrate diet together with plentiful doses of sodium bicarbonate and atropine, all of which measures are designed to diminish gastric acidity and motility. Many have reported favorably on this regime, but more recent and accurate measurements in the human being have cast some doubt on its effectiveness. With regard to drugs, ephedrine appears to be the most satisfactory for clinical use. There are other drugs, as for example physostigmin, which have a greater effect in diminishing the pancreatic secretion, but they all have unpleasant side reactions of one sort or another which make them undesirable for clinical use. Some writers have reported favorably on the effect of deep x-ray therapy in diminishing the pancreatic secretion and producing closure of fistulas, but the consensus of opinion among most recent writers who have tried it is that it has little or no effect, and the same may be said for the use of sclerosing fluids injected into the fistula. Surgery should not be considered for at least 6 months if the patient's health is not being impaired by the fistula, as many fistulas have closed after several months. If surgery is deemed advisable, the fistula may be dissected out and implanted into an adjacent viscus; the stomach, gall bladder, and jejunum have all been used for this purpose. Of these, the stomach has found most favor and has much to commend it because of its accessibility and the fact that the tryptic activity of the juice which might digest the suture line is immediately destroyed by contact with the acid secretion of the stomach. No untoward effects upon the digestive processes have been observed. However, "prevention is better than cure" in surgery as in medicine, and the fact that most pancreatic fistulas follow upon the drainage of pancreatic cysts must compel the question as to whether primary anastomosis of pancreatic cysts should not replace marsupialization and drainage as the standard treatment for pancreatic cysts.

CHARLES BARON, M.D.

Sacharow, G. P., and Rossysky, D. M.: The Treatment of Diabetes Mellitus without Insulin. *Vrachebnoe Delo*, 1946, 1, 2: 39.

Despite the universally well known treatment of diabetes mellitus with insulin, the possibility of influencing this condition favorably by other means should not be ignored. For the past 20 years the authors have been using, in the place of insulin, a special cytotoxic serum prepared from the pancreatic glands of animals which have been previously immunized against extracts of the human pancreas

procured from fresh corpses. This preparation is injected into the diabetic patient in small doses, in courses of from 20 to 30 injections and at intervals depending more or less upon the reactive capacity of the patient. At first these injections were intended as a means of stimulating the islands of Langerhans; but since ameliorating effects were noted on depancreatized experimental animals, the question came up as to whether the effect might not be exerted more generally on the entire substratum of the disease. Since there is a hypophyseal form of hyperglycemia and glycosuria the authors admit the possibility that the effect of their preparation might be procured indirectly by way of the hypophysis or other body glands (cortex of the suprarenals). It is also admitted that there is a reasonable basis for the fear that a stimulating influence on the islands of Langerhans, which are already diseased, might result in their eventual exhaustion; however, this expectation has not as yet been borne out in practice.

Although the authors do not as yet have data on their patients covering a sufficient period of time to justify giving individual case reports, they have observed a lowering of the hyperglycemia and glycosuria with their preparation, which has been similar to that obtained with insulin and the effects have been even more enduring. In fact they have had 2 patients under observation for 8 years who have not received either their preparation or insulin for the past 5 years, the original amelioration having lasted up to the present.

In any event, the authors believe that the time is now ripe for the profession to devote its attention to the possibilities inherent in the new methods of treatment of diabetes mellitus, and recommend that the problems involved be studied in the larger institutions.

JOHN W. BRENNAN, M.D.

Pompen, A. W. M., Jansen, G. A. L., and Dhont, J.: Adenoma of the Islets of Langerhans and Pregnancy. *Acta med. scand.*, 1946, 124: 334.

The authors report the case of a 35 year old woman who developed symptoms of hyperinsulinism 13 days after confinement in her second pregnancy. There were repeated attacks of loss of consciousness frequently in the early afternoon and also in the early morning. The attacks were accompanied by profuse perspiration and salivation. The blood sugar levels during attacks varied from 50 to 60 mgm. per cent and the attacks responded to the intravenous injection of dextrose solution. A provisional diagnosis of hypoglycemia during lactation was made and lactation was brought to an end. However, significant improvement did not occur when lactation ceased. After the patient returned home there was little improvement for a long time, but halfway through the third pregnancy distinct improvement occurred. Nine days after delivery the hypoglycemic attacks occurred more severely than following the second delivery.

A diagnosis of a hypoglycemic state due to an islet cell tumor of the pancreas was made. Such a tumor

of the cyst and closure of the abdomen, and x by anastomosis with the stomach over a rubber tube.

Pancreatic fistulas raise many problems which have engaged the attention of a number of investigators and which may be summarized as follows: the volume and control of pancreatic secretion, the cause of death in fatal cases and of pancreatic asthenia in less severe ones, the degree of importance of the external secretion of the pancreas to normal digestion, the enzymatic activity of pancreatic secretion, and the treatment of pancreatic fistulas.

It is generally acceded that the pancreatic secretion is under the control of both nervous and humoral influences. The humoral control is effected by means of secretin which is liberated from the duodenum in response to the discharge of the acid contents of the stomach into it. The secretin thus thrown into the blood stream stimulates the pancreas to produce a large volume of secretion rich in sodium bicarbonate. Stimulation of the vagus, on the other hand, has a much smaller effect on the volume secreted, but produces a fluid which is rich in digestive ferments. Thus it will be seen that the volume and alkalinity of the secretion are largely under humoral control while the digestive activity is under nervous control. The secretin mechanism contains within it the elements of an automatic regulator or cut out, for the alkaline secretion poured out in response to the acid chyme entering the duodenum rapidly brings about its neutralization and consequently the cessation of the stimulus. It is quite clear that in cases of fistula this automatic control is rendered inoperative. The pancreas responds to the secretin stimulus, but the resultant flow of fluid does not reach the duodenum.

The cause of death is not yet sufficiently clear and is almost certainly due to a number of contributory causes. The dehydration is an obvious factor. Human pancreatic fistulas may secrete up to 2,000 c.c. (3 3/4 pints) of fluid in a day, which represents a very substantial fluid loss. In addition to this there is the fluid lost in the vomiting which is such a common concomitant of the condition. This dehydration is rapidly reflected in the sunken eyes and inelastic skin of the sufferer. Pancreatic fluid contains an appreciable quantity of protein, albumin, and globulin, and this mounts up in the large volume secreted to produce a serious drain on the plasma proteins. Pancreatic fluid also is a markedly alkaline secretion—the pH of the specimen recorded was 9. This alkalinity is due to the high sodium bicarbonate content, and it might be that such a constant drain in alkali would produce a significant acidosis. While there is no doubt that it does cause some acidosis, the effect should not be overestimated. In the first place this is counterbalanced to some extent by the frequent concomitant vomiting, and also there is evidence to show that much of the bicarbonate is produced locally in the pancreas as a product of the metabolism of its cells and is not derived from the blood. This is in keeping with the surprisingly slight changes in blood chemistry which have been

repeatedly reported even in patients who were gravely ill. However, while the blood chemistry changes are slight and may be masked by the concentration of the blood, this does not mean that such changes which are present are not very important. This discussion of blood chemistry may seem to be unduly academic, but at least it has an important practical significance as it emphasizes the importance of maintaining the fluid and sodium reserves of the body in all such cases. While there is no doubt that the main factors contributing to the mortality and morbidity of pancreatic fistulas are the anhydremia and blood changes outlined, there remains an uneasy feeling that this is not perhaps the whole story.

The pancreas has been successfully extirpated in the human being without impairment of the digestion, and it may well be asked whether the external secretion is of any vital importance in the digestive processes. The occurrence of fatty diarrhea in cases of pancreatic fistula and other pancreatic diseases is quite inconstant and apparently quite capricious, being unrelated to the severity of the condition (some cases of partial fistula have severe steatorrhea, while other cases of total fistula have no such symptoms). Probably in most people the succus entericus together with the bile is quite capable of carrying on the digestive process to completion if the pancreatic juice is wanting, and thus we have but another example of the prodigality with which the body is supplied with alternative mechanisms to take the place of any which may be temporarily or permanently put out of action. No doubt, however, there are some individuals who are not able to compensate for the loss of pancreatic secretion, and in these the withdrawal of this fluid represents an irreparable loss resulting in serious digestive impairment.

Eighty per cent of such fistulas close spontaneously in due course, and such closure has been noted even up to a year after the fistula has been established. Treatment in the first instance should, therefore, be conservative and should be directed toward: (1) the restoration and maintenance of fluid requirements and normal blood chemistry, (2) the protection of the wound when digestive activity is a feature of the condition, and (3) diminution in the volume of the secretion to encourage closure. The second is often no problem at all, but if digestion of the wound is troublesome probably the best method of treatment is that devised by Caryl Potter (1929) for the treatment of duodenal fistulas. This is based on the fact that trypsin is only active in an alkaline medium, and the method consists in irrigating the wound with a continuous drip of N/10 hydrochloric acid and dressing it with gauze soaked in 10 per cent Witte's peptone to absorb any tryptic activity which may still be left. Less severe cases can be satisfactorily handled by protection of the skin with liberal applications of vaseline or aluminum paste. The third objective of conservative treatment, namely, to diminish the secretion in order to favor closure of the fistula, may be conveniently

discussed under the headings: (1) diet, (2) drugs, and (3) other measures. Since the volume of the secretion is largely governed by the secretin mechanism, which is in turn dependent upon the motility of the stomach and the acidity of its contents, any measures which will lessen these might be expected to bring about a reduction in the volume of secretion.

Wohlgemuth instituted his dietary regimen for pancreatic fistulas and this has remained the standard since his day. His method was briefly to give a high fat, low carbohydrate diet together with plentiful doses of sodium bicarbonate and atropine, all of which measures are designed to diminish gastric acidity and motility. Many have reported favorably on this regime, but more recent and accurate measurements in the human being have cast some doubt on its effectiveness. Harvey, E. N., Whiteley, A. H., Grundfest, H., and McMillen, J. H.: Piezoelectric Crystal Measurements of Pressure Changes in the Abdomen of Deeply Anesthetized Animals during Passage of a High Velocity Missile. *Mil. Surgeon*, 1946, 98: 509.

Rapid pressure changes accompany the passage of a high-velocity missile through the body. Shock arises when the missile strikes tissue; a high pressure exists on the face of the moving missile; and, finally, there are pressure changes which accompany the formation and pulsation of the temporary cavity behind the missile. In order to measure accurately these pressure changes in small animals, it is necessary to use a recording device of small size the presence of which will not greatly disturb the pressure gradient. It is also essential that the response of the pressure gauge be instantaneous, since some of the pressure changes must be measured in microseconds. For this purpose the tourmaline piezoelectric gauge is ideal.

To measure pressures in the body the tourmaline crystal gauge is placed in the stomach of a deeply anesthetized cat, which is then shot through the lower part of the abdomen. With the development of hydrostatic pressure, electric charges which are proportional to the pressure appear on the tourmaline surface. The charges are amplified and applied to the vertical plates of the cathode ray oscilloscope with a single horizontal sweep to record the time axis. The fluorescent trace of the electron beam on the face of the tube is then photographed with a wide aperture lens on Super XX panchromatic film.

The pressure changes during the passage of a high-velocity missile through the abdomen of a deeply anesthetized cat have been correlated with events in the body by microsecond roentgenograms and high speed motion pictures. Positive pressures of hundreds of pounds per square inch, lasting a few microseconds, result from the shock wave which arises when a missile strikes the body wall. This wave then travels through tissue with a velocity of approximately 4,800 feet per second. The shock wave may be reflected from air pockets, bone, or tissue surfaces. A new shock wave will also form whenever the missile traverses a gas pocket. No characteristic shock wave pressure pattern is produced, but each animal will differ, according to the gas distribution in the alimentary tract and the course of the missile. A series of pressure responses have also been recorded by a crystal gauge in the stomach during a shot through the thigh of a cat.

Slow pressure changes, measured in tens of pounds per square inch and in milliseconds, follow the shock wave pressures after a shot through the abdomen. They are connected with the temporary cavity behind the missile. With the expansion of this cavity, a subatmospheric pressure develops that becomes positive as the cavity collapses. Then two small pressure oscillations occur.

Microsecond roentgenograms show no second expansion after the collapse of the cavity, although vigorous abdominal movements occur. The cavity is believed to consist almost entirely of water vapor, which collapses completely, except for a few pockets of gas responsible for the two small pressure oscillations measured above. Pressure records, microsecond roentgenograms, frames from motion pictures, and spark shadowgrams of shock waves in water illustrate the findings. JOHN L. LINQUIST, M.D.

Gillis, L.: Hernia through the Foramen of Winslow. *Lancet*, Lond., 1946, 2: 48.

Hernia through the foramen of Winslow is rare and has a very high mortality. It occurs in two forms: in one the hernia passes into the foramen of Winslow and remains in the lesser sac and in the other it re-enters the peritoneal cavity through the gastrohepatic omentum. Either the small intestine or the large intestine may enter the foramen of Winslow.

The present case may throw some light on both the predisposing factors and the anomalies which are said to exist.

A tiger, aged 41, was admitted to the hospital with a history that he had been seized with a sudden severe pain in the epigastrium while at stool. The pain was sharp and continuous, did not radiate, and had not altered in character since its onset. He had vomited 4 times before admission.

On examination he was in a severe state of shock and obviously in great pain. There was tenderness in the epigastrium and some guarding, but no rigidity. Acute intestinal obstruction or perforation was tentatively diagnosed.

Under general anesthesia the patient was operated on. The peritoneal cavity was opened through a midline incision. There was some bloodstained fluid present in the peritoneal cavity. No perforation could be found, but there was an unusual band running across the posterior abdominal wall, toward the right hypochondrium. This consisted of small intestine with its mesentery. As this was abnormal anatomically, the question arose whether this was not some form of transposition of the viscera. Further investigation showed that it was an internal hernia into the foramen of Winslow.

The bowel could be coaxed back into the greater sac by stretching the foramen of Winslow with the fingers, by pressure on the gastrohepatic omentum, and by gentle traction on the entering loop.

The loop, when reduced, was found to be about 18 inches of jejunum; it was purple and frayed but not devitalized. The proximal loops were distended, and the distal loops were collapsed. Resuscitative meas-

ures with warm towels improved the condition of the bowel, except for an area about the size of a shilling in the mesentery.

The patient made an uninterrupted recovery and is quite well to date.

The history of sudden pain while at stool suggests that the increase of intra-abdominal pressure allowed the small intestine, attached to an abnormally long mesentery, to be driven into the foramen of Winslow.

HARRY W. FINK, M.D.

Hamilton, I., and Hardy, J. E. S.: Hernia through the Foramen of Winslow Emerging through the Gastrohepatic Omentum. *Med. J. Australia*, 1946, 1: 805.

A 29 year old male fitter in good health previously was seized suddenly with agonizing pain and attacks of vomiting. His temperature was normal but his pulse was only 52 per minute. The initial diagnosis was ruptured peptic ulcer, which because of a change in symptoms was later changed to obstruction of the small bowel and more specifically to strangulation of an internal hernia.

At operation, 21 hours after the onset, through an upper abdominal paramedian incision on the right side and after displacement of the rectus laterally,

coils of dark blue, distended small gut could be seen, and a considerable amount of hemorrhagic serous effusion continued to well into the wound. The distended loops were traced upward and downward, and it became obvious that both limits of the bowel disappeared upward between the stomach and liver. On further investigation it was discovered that the coils passed through a rent in the lesser omentum into the lesser sac. With retractors and packs the foramen of Winslow was sought, and it was discovered that two coils of gut passed through the opening. Attempts to reduce these failed at first, but after digital dilatation of the foramen the gut could be extricated from the lesser sac and returned to its rightful position. About $3\frac{1}{2}$ feet of small bowel had been involved, the involvement extending downward from about 3 feet from the duodenojejunal flexure. Both afferent and efferent loops were constricted at the foramen. The congested gut was delivered and wrapped in moist, warm saline packs, and the lesser omentum was inspected. An oval hole, about $2\frac{1}{2}$ inches by $1\frac{1}{2}$ inches was seen. This was sutured with catgut. The small bowel was returned to the abdomen and the wound was sutured in layers.

The postoperative course was stormy but the patient made a good recovery. HARRY W. FINK, M.D.

GYNECOLOGY

UTERUS

Kahanpää, V.: The Pathogenesis of Ovarian Endometriosis (Ueber die Pathogenese der Ovarialendometriose). *Acta obst. gyn. scand.*, 1946, 26: 139.

Although the implantation theory of endometriosis proposed by Sampson is rather widely accepted at the present time, there is still controversy concerning the mechanism of implantation and the pathogenesis of hemorrhagic cysts of the ovary. The author studied histological preparations of operative specimens in 6 cases of ovarian endometriosis and hemorrhagic cysts obtained at the Women's Clinic in Helsinki. Serial sections were not made but samples of tissue were taken from each ovary and cyst and stained with hematoxylin van Gieson stain. The case histories, operative findings, and significant photomicrographs are presented.

Typical endometrial tissue was found both in proximity to and at a distance from the hemorrhagic cysts. Likewise, typical endometrial tissue was found on the surface of, and penetrating deeply into, the ovarian tissue. One specimen, removed at the beginning of menstruation, presented the appearance of a hemorrhagic cyst in the process of early development, the cyst cavity containing epithelium, blood, and secretion. In several instances a new observation was made, namely, that primary endometriosis implantation may occur in the corpus luteum.

The observations made in this study are thoroughly in accord with Sampson's theory concerning the origin of ovarian endometriosis and the gradual development of hemorrhagic cysts from the endometrial tissue. It appears that primary implantation in the ovary may occur in a recently ruptured follicle or a young corpus luteum. The rupture of the follicle provides a break in the tunica albuginea, while the local blood imbibition of the tissues and the uneven surface favors the implantation and development of the endometrial fragment in the new site.

With respect to the viability of endometrial fragments arriving at the ovary, it is probable that these fragments do not originate from the uterine mucosa during menstruation, but rather that they are derived from tubal endometrium during the menstruation interval, as suggested by Philipp and Huber. Following primary implantation in the ovary, propagation may occur by direct growth in continuity, or secondary implantation may occur from rupture of hemorrhagic cysts during the menstruation interval.

JOHN L. LINDBQUIST, M.D.

Gianaroli, L.: A Contribution to the Problem of Serological Diagnosis of Cancer of the Uterus (Contributo allo studio della diagnosi sierologica del cancro dell'utero). *Riv. Ital. gin.*, 1943, 26: 429.

The method of Hirsfeld and Halber (with minor modifications) was utilized for serological diagnosis

in a series of 56 cases of uterine or vaginal carcinoma, and a control group of 90 cases. The antigen was prepared from known carcinomatous tissue by alcoholic extraction, in several dilutions. Fresh guinea pig serum was employed as complement. Another method of diagnosis was accomplished with the use of rams' red cells with a specified hemolysis. The quantities and technique were those commonly adopted for the Wassermann reaction. Readings were taken at 12 and 24 hours.

Of the experimental group, 24 patients gave strongly positive reactions, 23 positive, and 9 weakly positive. The reactions of 84 of the control group were negative. Although these results are more consistent than those obtained by other methods, the specificity of the complement fixation method is not established.

In view of the small incidence of positive reactions among the control group, however, the usefulness of the method is demonstrated, if not for the discovery of early lesions, at least as corroborative evidence in cases of doubtful lesions.

EDITH B. FARNSWORTH, M.D.

Ayre, J. E.: Vaginal and Cervical Cytology in Uterine Cancer Diagnosis. *Am. J. Obst.*, 1946, 51: 743.

This report consists of an analysis of 100 cases of genital malignancy studied in the Gynecologic Cytology Division of the Royal Victoria Hospital. Excellent colored photomicrographs of representative cases are presented.

In the 100 cases giving a tissue diagnosis of malignancy, the cytology smears showed an average error of 6 per cent. Smears taken routinely from the external cervical os have been found to be more reliable for diagnosis than vaginal smears. An interesting observation was that many of the cases of malignancy in the postmenopausal age group showed evidence of associated estrogenic activity.

The smear technique has been shown to be of value in detecting cancer at an early stage. It has proved helpful too in benign cases simulating malignancy clinically. Negative cell smears in such cases have been proved correct by biopsy. The method has also been found to be of value in assessing radiation therapy.

A new technique, the centrifuge cytology technique, is presented briefly with illustrations.

EDWARD L. CORNELL, M.D.

Fremont-Smith, M., Meigs, J. V., Graham, R. M., and Gilbert, H. II.: Cancer of the Endometrium. *J. Am. M. Ass.*, 1946, 141: 805.

The authors present a case treated with large amounts of estrogenic substance almost continuously for 8 years with a final diagnosis of carcinoma of the endometrium. They found atrophic vaginal epithelium after estrogen was withdrawn, and supposed

that the patient was producing little or no estrogen, but after the administration of extrinsic estrogens she developed endometrial cancer.

They reviewed the literature in regard to the relationships between estrogens and cancer of the breast, and cancer of the endometrium. In regard to the first relationship, it was noted that when Lacasagne gave diethylstilbestrol, chemically unrelated to the natural estrogens, to male mice it caused cancer. All authors agree that in addition to estrogenic stimulation of the breast, two other factors are essential for the production of mammary cancer in mice; these are (1) a "milk factor" and (2) a hereditary factor. There have been several reports of cancer of the breast which occurred in women under estrogen therapy. In regard to the relationship between estrogens and cancer of the endometrium, it is noted that no report of endometrial carcinoma in animals subjected to estrogen treatment has appeared, but cancer of the cervix has been produced by estrogens.

In man, carcinoma developing on the basis of hyperplasia has been particularly observed by Novak and Yui. They found hyperplasia in 25 of 104 cases of endometrial cancer. Randall believes that when postmenopausal bleeding occurs, the woman who has experienced menorrhagia during the climacterium presents a $3\frac{1}{2}$ times greater chance of having adenocarcinoma of the uterus than does one who has had no excessive bleeding during this period.

EXTERNAL GENITALIA

Siegler, S. L.: A New Method of Treatment for Vaginitis and Cervicitis. *Am. J. Obst.*, 1946, 52: 1.

A new antivaginitis sulfathiazole polyethylene glycol acid jelly is described. The jelly is nonirritating, nonstaining, and of an agreeable odor. It spreads over the cervical and vaginal surfaces and is completely soluble in the secretions. It does not easily leak out of the vagina unless the discharge is profuse. It has a mild but definite astringent effect on the vaginal mucosa.

Use of the jelly has resulted in excellent control of vaginitis of trichomonal, monilial, gonococcal, and nonspecific origin in 93 per cent of the cases observed, and in permanent cure in 83 per cent. Use of the jelly alone has given good results in the management of cervical infections in 22 per cent of the cases treated.

The period of convalescence can be markedly shortened, and annoying symptoms reduced by use of the jelly before and after such procedures as conization, coagulation, cauterization, plastic repair, and other intravaginal surgery. Healing was complete within an average time of 5 weeks with a minimum of sequelae. The convenience and simplicity of the single dose disposable paper applicator facilitates intravaginal medication both in the office and in the patient's home.

MISCELLANEOUS

Deter, R. L., Caldwell, G. T., and Folsom, A. I.: A Clinical and Pathological Study of the Posterior Female Urethra. *J. Urol.*, Balt., 1946, 55: 651.

The purpose of this study by the authors was to emphasize the importance of the glandular structures encountered in the posterior female urethra. We have very meager knowledge of the embryology of the female urethra. According to Evatt, the female urethra is the counterpart of the whole prostatic urethra in the male. Histologically, glands were found in 92 per cent of the urethras studied. The main characteristic of these glands was that they appeared to be tubular glands and compound tubular glands. The closer to the bladder the sections were taken, the greater was the number of glands that were seen. In 100 per cent of the specimens showing glands their location was found to be on the lateral and posterior surfaces.

The symptoms of posterior urethral disturbances were frequency, more diurnal than nocturnal, and bladder irritability. Cystoscopic examination shows intense redness of the mucous membrane with small elevated areas which appear to be cystic and give the urethra a granular appearance.

These studies lend support to the opinion of some urologists that the pathological changes which take place in the posterior female urethra are produced by infection in the posterior urethral glands. It is also believed that the hormones play some part in the etiology. These changes are frequently found just preceding or just after the onset of puberty, in post-nuptial cases, in pregnancy, and at or after the menopause.

Rauramo, M.: A Rapid and Easily Performed Method of Operation in Cases of Urinary Incontinence (Au sujet d'une méthode d'opération rapide et facile à pratiquer dans les cas d'incontinence urinaire). *Acta obst. gyn. scand.*, 1946, 26: 129.

The author describes and illustrates a rapid and easily performed method of operation in cases of urinary incontinence.

The procedure described is a modification of the operation published by Berkow in 1941 (*Am. J. Obst.*, vol. 41).

The author considers this method an improvement of the procedure of transplanting the urethral orifice as advocated by Pawlik, Dudley, and others.

The essential point in the procedure consists in the careful detachment of the lower part of the urethra and its transplantation much higher, just beneath the clitoris, where it is fixed. In addition, the urethra is strengthened throughout its entire length by a supporting suture of the muscles of the urogenital diaphragm, which recalls notably the procedure of Opitz. Both Berkow and Burger (*Zbl. Gyn.*, 1943), who modified the procedure, operated through a triangular incision, the apex of which was immediately beneath the clitoris and the lateral

Fig. 4

Fig. 5

Fig. 6

Fig. 7

angles of which were slightly below and lateral to the urethral orifice. In this area the mucosa was removed except for the little collar left around the urethra (Fig. 1).

The author has tried this method for about 2 years in several cases and the results seemed to be of such value that he wishes to call attention to this simple procedure. By virtue of his own experience, he modified the operative procedure so that he no longer removes the triangular area of mucosa described, but makes a primary incision as shown in Figure 2. He makes a vertical incision which begins at a point just below the clitoris and then goes around on both sides of the urethral orifice in the form of a circle, continuing below in a straight line to a point as low as is necessary in each particular case. Through this incision the two edges of the wound are undermined to an adequate point, after which the detachment of the urethra can be done with care, so that no tension is exerted on the border of the surrounding mucosal collar. The urethral orifice with its collar is reunited to the mucosa just below the clitoris (Figs. 3 and 4). After the urethra has been transplanted as much of the mucosa as necessary is removed (Figs. 5, 6, and 7). When a vaginal or uterine descensus (or a prolapsus) is present, associated with incontinence, the incision is prolonged in the usual manner to the cervix. The bladder which is exposed is elevated and the muscles of the urogenital diaphragm are sutured

together. The anatomical condition, before the supporting suturing is done, presents the appearance of a figure 8. In its entirety, the operation is so minor that it can be performed without difficulty in young as well as in old patients. After operation, a small rubber catheter is placed in the urethra for 2 or 3 days and then removed.

To illustrate the usefulness of the operation, the author reports in detail a case treated by the method described. The patient, a woman of 50 years of age, had already had two operations according to the method of Martius without satisfactory results, but very satisfactory results were obtained by the author's operation in this case. Although only 2 years have elapsed since the operation, the patient is well and in a very happy condition.

BLACKWELL MARKHAM, M.D.

Blanchard, O.: The Value of the Smears from the Vaginal Secretion in Establishing the Differential Diagnosis of the Ovarian Activity in Women (Valor del extendido vaginal para el diagnóstico de la actividad ovarica en la mujer). *Obst. gin. lat. amer., B. Air.*, 1936, 4: 107.

The author has found previous studies corroborating his findings that the smears obtained from the vaginal secretion of women present changes which are related to the different phases of the menstrual period. He also found that it is possible that the

morphological aspect of the vaginal smears varies in different anomalies.

The administration of several hormonal preparations produces changes in the morphology of the smears and the authors believe that a dose for such therapeutic measures could be ascertained as the relation of the estrogens and androgens to the changes are quite definite and even characteristic. Irritation, infections, or individual variations can change the aspect of the morphological elements of the secretion from the vagina.

WILLIAM E. RICKETTS, M.D.

Douay, E.: Pelvic Endometriosis. (Endométriose pelvienne). *Rev. fr. gyn. obst.*, 1946, 41: 92.

Stimulated by papers and discussions of endometriosis given at the recent French Congress of Surgeons, the author reviews his experiences with this disease.

As to the pathogenesis of this disease, he leans to the migratory theory. According to this theory, uterine mucosal cells, especially at the time of menstruation, are capable of migrating from the uterus by way of the lymphatics, the blood vessels, and the reflux flow through the tubes to neighboring tissues and organs and into the peritoneal cavity. In certain cases the uterine mucosal cells, having migrated by one of these routes, fix themselves in their new habitat, and grow and develop into endometriomas. In these cases, the author believes, the displaced uterine cells are given a peculiar vitality and are made to develop into endometriomas under the influence of an abnormal activity of the ovary. CastRATION, which arrests the development and permits the regression of endometrial tissues, exerts its effect on these tumors not so much by causing a cessation of menstruation (thereby removing the source of uterine transplants) as by removing the abnormal activity of the ovary, which (in certain cases) permits migratory uterine cells to develop into endometriomas. The author hints that the prime cause of the abnormal activity of the ovary may be due to a function of the hypophysis.

Fourteen operative cases are reported in detail by the author. From his observation of these cases, he formulates his views as to the diagnosis and treatment of endometriomas.

Endometrial dysmenorrhea is the most characteristic clinical sign of pelvic endometriosis. It gains its maximum intensity at the end of menstruation and is prolonged several days later. The pain is located at the site of the endometrial lesion, but it radiates throughout the pelvis, to the rectum, to the ovaries, to the lumbosacral region, the buttocks, and the perineum. It is due to the distention of the small cavities lined with uterine mucosa which undergo, at menstruation, the same catamenial modifications that the mucosa of the uterus undergoes. The blood, on finding no outlet, distends the endometrial cavities and causes pain which is more acute as the tissue surrounding the endometrioma is more dense. Dysmenorrhea is at times violent and increases with each

menstrual period. In 8 of the 14 cases cited, this dysmenorrhea was present; it was associated with other causes of dysmenorrhea in 4 cases, and absent in 2 cases in which the tumor developed in pliable tissues more tolerant to distention.

This dysmenorrhea can be differentiated from (1) that resulting from mechanical causes, e.g., stenosis of the cervix and displacements of the uterus, as dysmenorrhea in the latter cases is present at the beginning of menstruation; (2) that resulting from uterine colic due to the expulsion of clots and shreds of uterine mucosa, which is present only during the period; (3) that resulting from ovarian disease which is usually premenstrual; and (4) that resulting from acute inflammation of the adnexa, which is usually postmenstrual.

Pelvic examination reveals the presence of conditions as cervical stenosis, uterine displacements, and adnexal disease.

Sterility, habitually observed in endometriosis (2 children in the 14 cases observed by the author) is not only due to tubular sterility but also to ovarian dysfunction.

Functional troubles of the ovary have repercussion in the general condition of the patient, giving rise to irritability, fatigue, and emaciation. These disappear after operation.

Vaginal examination in endometrioma of the posterior cul-de-sac reveals the presence of a hard retrocecal mass adherent to the vaginal wall and very sensitive to palpation.

Rectal examination reveals a tumor adherent to the rectum, while the overlying mucosa is pliable. No blood appears on the examining finger.

In endometrioma in the region of the ovary, examination reveals the presence of a fixed indurated mass painful on palpation. It can be differentiated from ectopic pregnancy in that the periods have continued regularly, unaltered in character and abundance. Acute inflammation of the adnexa is ruled out as endometrioma is unaccompanied by fever and genital inflammations. Tuberculosis of the adnexa is the most difficult lesion to differentiate, because hardness of the lesion and slow and progressive development without a great amount of fever may be present in both conditions.

In the region of the uterus, endometrioma resembles fibroma, but progressive development, inefficacy of medical treatment, and extreme sensitiveness on palpation favor endometrioma.

Failure to make a diagnosis at the time of operation is exceptional because (1) there is bloody liquid in the peritoneal cavity, often brownish and sticky; (2) the ovary, often polycystic, is adherent without signs of inflammation and the tubes are patent; (3) the detachment of adhesions of the ovary leads to the rupture of the bloody cysts; (4) there are resistant, fibrous cords with retraction and displacement of the mobile organs; (5) the endometrioma does not protrude above the surface of the peritoneum but forms an induration beneath it; and (6) there are little brown bodies, the size of a pinhead, in the peri-

toneum, which are the little bloody cysts characteristic of endometrioma.

The following methods of treatment are listed: (1) hormonal treatment with testosterone, (2) castration by means of x-rays or radium, (3) surgical castration, and (4) complete excision of the lesions. If the lesions are limited, operation will be conservative, and the ovarian and genital function will be retained. If the lesions are extensive, the operation will be radical—hysterectomy with castration.

The method of treatment advised by the author is surgical intervention after a trial treatment with testosterone in moderate doses (from 80 to 100 mgm. monthly) over a relatively short period (3 months). If the painful crises persist and the tumor continues to grow, surgical intervention is indicated.

Operation allows verification of the diagnosis, evaluation of the situation and extent of the endometrial lesions, reveals the presence of associated lesions, and allows an opportunity to act accordingly.

One must be content to remove all that is easily removable. In general, total or subtotal hysterectomy with castration is performed if the woman is relatively old or near the time of the menopause. If the woman is young a fragment of healthy ovary, either *in situ* or as a graft in the labia majora, is necessary to prevent the discomforts of castration. An ovarian graft in the labia is more desirable for if it undergoes cystic degeneration or develops into an endometrioma, it can be removed easily under local anesthesia. If such conditions occur in the fragment of ovary left *in situ*, radiotherapy may be employed to suspend the abnormal ovarian activity. The vitality of the graft lasts from 6 months to 2 years. Hormonal therapy is used, if necessary, after the ovarian graft ceases to function.

Some of the extensions of the endometriomas are important from the surgical point of view.

As the fibrous bands of endometrial tissue increase in size, they displace the mobile organs, distort them, invade them, and disturb their function, e.g., invasion of the colon and the rectum. It is usually possible to remove the tumor without wounding the invaded organ.

The endometrial tumor has a tendency to encircle an organ, e.g., the ureter, deform it, and interfere with its function without invading its tissue. The tumor can often be removed without harming the ureter as its walls are usually intact.

At the time of operation, the surgeon should remove all endometrial lesions capable of producing subsequent trouble unless this would seriously interfere with the recovery of the patient.

BLACKWELL MARKHAM, M.D.

Mayo, S.: The High Peritonization in Gynecological Surgery (La peritonización alta en cirugía ginecológica). *Sem. med., B. Air.*, 1946, 53: 509.

The author has found that in Buenos Aires surgeons performing high peritonization or walling off of the pelvis in gynecologic surgery obtain very good results. The suprapubic drainage used formerly is used only very occasionally at the present time. The author advises such a procedure when gynecologic exeresis is done and especially in cases in which there is a cancer of the uterus. High peritonization was done in 42 cases: for neoplasia of the neck of the uterus in 24, for neoplasia of the body of the uterus in 4, for myoma with inflammation of the adnexa in 12, for myoma with endometriosis in 1 case, and for a calcified placenta in 1 case.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Ziskin, D. E., and Nesse, G. J.: *Pregnancy Gingivitis: History, Classification, and Etiology.* *Am. J. Orthodont.*, 1946, 32: 390.

Gingivitis occurs in from 50 to 70 per cent of pregnant women as compared with 15 to 18 per cent of nonpregnant women. The authors in an extended study, of which this article is a correlative summary, present a classification of pregnancy gingivitis and offer a concept of its etiology.

The classification is based primarily on clinical observations made throughout pregnancy. Five major types of pregnancy gingivitis are distinguished clinically. They range from the commonest form characterized by bleeding from the gums to the so-called "pregnancy tumor." This classification represents the progressive changes in pregnancy, so more than one type may be present in the same case. The microscopic changes in biopsies from several hundred cases of pregnancy gingivitis are essentially the same. In the gingivae and oral mucous membranes during pregnancy there is a loss of surface keratin, hydropic alteration of the stratum spinosum, hyperplasia of the stratum germinativum, and inflammatory changes in the lamina propria.

In collecting evidence for the probable etiology of pregnancy gingivitis the authors have considered the general physiological changes in pregnancy, with special attention to the established interrelationships of endocrine and metabolic functions. This includes a consideration of the action of the hypophysis, the thyroid, the adrenal cortex, the ovaries, the placenta, and the vitamins. The changes that other glandular imbalances may produce in the gingivae have been noted, and in this connection the effects of hormonal administration on the gingivae of Rhesus monkeys are mentioned.

It appears that the immediate cause of the gingival changes is a diminished utilization of estrogen or a modification of estrogen metabolism. The following possibilities are set forth:

1. Estrogen during pregnancy is present in bound, inactive form, so that it may not be available to the gingivae to the expected extent, and hence does not have the usual beneficial effect on the gingivae.
2. There may be a reduced ability of the oral tissues to utilize the available estrogen because of the increased amounts and modifying effect of progesterone.
3. The large amounts of chorionic gonadotropin may affect the gingivae directly or indirectly.
4. The increased activity of the thyroid and the adrenal cortex may modify the effect of available estrogen on the gingivae.
5. Nutritional factors may alter the amount of endogenous estrogens available for the gingivae.

L. JAMES TALBOT, M.D.

Parvialinen, S.: *The Frequency of Nephrogestosis during the Years of War* (Fréquence de la néphrogestose pendant les années de guerre). *Acta obst. gyn. scand.*, 1946, 26: 174.

The frequency of nephrogestosis markedly diminishes during the years of war. Restrictions of diet, necessitated by the emergency of war, are considered to be the cause of this diminution.

The frequency of nephrogestosis was studied by the author in 2 localities, Helsinki and Turku, for the period from 1935 to 1944. A total of 31,125 deliveries were studied. Of the patients, 16,965 were seen at the Gynecological Clinic of the University of Helsinki, 11,484 at von Heideken's Maternity Hospital at Turku, and 2,676 at the Departmental Hospital at Turku. The patients at von Heideken's Hospital were inhabitants of the city of Turku, while those at the Departmental Hospital were from rural areas.

Among the 16,965 deliveries at the University of Helsinki made in the period from 1935 to 1944, there were 2,106 cases of nephrogestosis (12.6 per cent), while at this same institution, for the period from 1926 to 1935, the percentage of nephrogestosis was 19.2.

Among the 11,484 deliveries made at von Heideken's Hospital in the period from 1935 to 1944, there were 2,246 cases of nephrogestosis (19.6 per cent), while for the period from 1926 to 1935 the percentage of nephrogestosis was 20.8.

Among the 2,676 deliveries at the Departmental Hospital at Turku in the period from 1935 to 1944, there were 453 cases of nephrogestosis (16.9%); no record was given for this condition from 1926 to 1935.

The frequency of nephrogestosis reached its maximum at Helsinki in 1936 with a percentage of 24.2, and its minimum in 1943 with a percentage of 5.6.

At Turku, the frequency of nephrogestosis reached its maximum in 1939 and its minimum in 1943.

Nephrogestosis is more general among primiparas than among multiparas. From 1935 to 1944 at Helsinki, nephrogestosis occurred in 15.9 per cent of the primiparas and in 8.8 per cent of the multiparas. At von Heideken's Hospital during the same period nephrogestosis occurred in 23.4 per cent of the primiparas and in 15.3 per cent of the multiparas; at the Departmental Hospital it occurred in 20.7 per cent of the primiparas and in 13 per cent of the multiparas. During the war years the disease diminished in frequency in both primiparas and multiparas.

The war affected the young women more than the older women as nephrogestosis occurred less often in the young mothers, but the more serious cases of nephrogestosis occurred in the older mothers.

The frequency of nephrogestosis diminished also among the cases of twin pregnancy during the war years.

The frequency of the less severe cases of nephrogestosis (albuminuria and nephropathy) markedly

diminished during the war years, but the more severe cases (pre-eclampsia and eclampsia) showed little diminution in frequency during the war.

While the total mortality during delivery decreased during the war years, the mortality among patients with nephrogestosis increased.

While the total infant mortality decreased during the war years, the infant mortality among the cases of nephrogestosis markedly increased during this period.

In summary, it was found that nephrogestosis of all grades appears to decrease during wartime, chiefly because of the impaired nutrition. Yet the nerve strain of war tends to heighten the blood pressure and increase the liability to convulsions which contributes to the increase in number of the more severe cases of nephrogestosis.

BLACKWELL MARKHAM, M.D.

Duckering, F. A.: The Significance of Myoma Uteri in Pregnancy. *Am. J. Obst.*, 1946, 51: 819.

The incidence of myoma uteri among the obstetric patients at the Woman's Clinic of the New York Hospital is 1.4 per cent. The role of myoma uteri in causing complications of pregnancy is clarified by comparing the patients who had myomas over 6 cm. in diameter to patients with myomas that were less than 6 cm. in diameter.

Since myoma uteri are found more frequently in the late childbearing ages, there is a high incidence of elderly primigravidae (15.7 per cent). The significance of myomas in causing sterility is difficult to evaluate.

Myomas are more easily detected early in pregnancy or the postpartum period when the entire surface of the uterus can be explored on bimanual examination. Frequently they are only discovered when complications of pregnancy and delivery focus attention on them. Antepartum pain due to myoma was present in 11 per cent of the patients in this series. However, there were very few cases in which pain was severe enough to necessitate operative intervention. The incidence of abortion (17.1 per cent) and of premature labor (5 per cent) in this series was twice the clinic incidence, which is 8 per cent and 2.5 per cent, respectively.

Presentation is affected only by large tumors which interfere with the adaptation of the fetus to the longitudinal axis of the uterus. There is no evidence that myoma uteri is a factor in causing prolonged labor or premature rupture of the membranes.

There is a high operative incidence among patients with large myomas (47 per cent) when compared to patients with small fibroids (23.4 per cent) who have an incidence of operative deliveries similar to the general clinic.

Thirteen patients had definite dystocia due to myoma. Postpartum hemorrhage is rarely caused by myomas. The incidence of postpartum hemorrhage among the patients was 3.8 per cent, an incidence similar to that found in the total clinic, which varied from 1.7 per cent to 4.4 per cent during

the same period of time. The incidence of puerperal sepsis was 15.8 per cent, or more than twice as high as is found among the general clinic population. The increase in morbidity occurs almost entirely in the group of patients with large myomas. However, it cannot be accounted for on the basis of an increased operative incidence in this group as it is also proportionately higher following abortion and spontaneous delivery. The fetal mortality among patients in this series is 9.6 per cent compared to that of the clinic, which is 3.46 per cent. There were 3 maternal deaths. The presence of myomas was incidental and entirely unrelated to the cause of death in 2 of the patients. EDWARD L. CORNELL, M.D.

Dannreuther, W. T.: Therapeutic Abortion in a General Hospital. *Am. J. Obst.*, 1946, 51: 54.

The author originally compiled the statistical data to secure the figures indicating the frequency of therapeutic abortion during a 10 year period. In this group of 84 cases, many of the abortions were done before the adoption of the existing rules at the New York Postgraduate Hospital. Possibly some of them would have been refused to-day.

It would seem an almost impossible task to prove exactly to what extent a therapeutic abortion contributes to the prolongation of life expectancy. The author has no intention of implying that a therapeutic abortion can cure epilepsy or a brain tumor or any other disease, but he believes that it may protect the health and lengthen the life of many patients whose existence might otherwise be much more distressing. EDWARD L. CORNELL, M.D.

LABOR AND ITS COMPLICATIONS

Farber, E. P.: The Induction of Labor with Methergine. *Am. J. Obst.*, 1946, 51: 859.

It is not the purpose of this article to advocate the routine induction of labor; rather it is to set forth a method of inducing labor which will be relatively safe to both the mother and infant which may be used when the induction of labor is indicated.

A new synthetic ergot preparation, methergine, was employed for the induction of labor in 30 consecutive cases and satisfactory results were obtained in 27 instances. Methergine was shown to have the ability to induce labor in the presence of intact as well as ruptured membranes. There were no maternal or fetal complications, and the length of labor was materially shortened when methergine was used. Methergine may have considerable value in cases of uterine inertia.

EDWARD L. CORNELL, M.D.

Ullery, J. C.: Continuous Spinal Anesthesia in Cesarean Section. *Am. J. Obst.*, 1946, 51: 100.

From the experience of delivering 300 patients by cesarean section under continuous spinal anesthesia with no maternal deaths, the authors believe that this is a safe anesthetic procedure for both mother and child. All of the babies, excepting the stillborn,

showed no anoxemia, cried at once, were of good color, and required no resuscitation. The postoperative morbidity of the mothers was low, and the complications were no greater than those with inhalation anesthesia. The advantages of continuous spinal analgesia with its safety, low dosage, and controllability are emphasized and should make its use desirable in cesarean section. The technique is easy and requires only the care and caution that should be given when administering any anesthetic.

EDWARD L. CORNELL, M.D.

NEWBORN

Russ, J. D., and Strong, R. A.: Asphyxia of the Newborn Infant. *Am. J. Obst.*, 1946, 31: 643.

This study is based on 1,144 resuscitations of the newborn. In general, primiparas produce more asphyxiated babies than do multiparas. However, in the multiparous mother, for some undetermined reason, the third, sixth, eighth, and eleventh babies seem to have a greater tendency toward asphyxiation than the others.

It is becoming increasingly evident that the prolongation of labor is by far the most outstanding single cause of asphyxia of the newborn. It has been too easy to blame the analgesic drugs, but the asphyxia which is produced by drugs is by no means either as frequent or as severe as that produced by a prolonged labor.

It is the authors' very firm and definite conviction that, if a routine catheterization of the newborn be done at every cesarean section immediately upon delivery, the death rate can be reduced from an

TYPE OF DELIVERY	ASPHYXIA RATE - %	DEATH RATE - %
Version and extraction	80-90	25-35
High forceps	80-90	25-30
Breech extraction	60-65	12-15
Midforceps	50-60	10-12
Cesarean sections	85-95	8-10
Low forceps	15-15	3-5
Spontaneous delivery	10-20	2-3
Low forceps with episiotomy	10-20	1-3

average between 8 and 10 per cent to as low as 2 per cent.

Anoxemia from many causes is responsible for 18.5 per cent of all deaths in newborn babies. It is the fourth most frequent cause of death in this age group. Among the most frequent contributing factors of anoxemia are the age and parity of the mother, duration of labor, type of delivery, prepartal analgesia, and the anesthetics used during delivery. Less frequently, prematurity, premature separation of the placenta, bleeding placenta previa, or a short cord, prolapse, torsion, knot, kink, or compression of the cord may cause it. Anoxemia prolonged more than 2 minutes after delivery will cause cerebral changes, but the prompt initiation and maintenance of respiration within 30 seconds after the cord is cut will prevent these changes, and if respiration is established before 2 minutes it may oxygenate the blood sufficiently to arrest any changes which have begun.

EDWARD L. CORNELL, M.D.

diminished during the war years, but the more severe cases (pre-eclampsia and eclampsia) showed little diminution in frequency during the war.

While the total mortality during delivery decreased during the war years, the mortality among patients with nephrogestosis increased.

While the total infant mortality decreased during the war years, the infant mortality among the cases of nephrogestosis markedly increased during this period.

In summary, it was found that nephrogestosis of all grades appears to decrease during wartime, chiefly because of the impaired nutrition. Yet the nerve strain of war tends to heighten the blood pressure and increase the liability to convulsions which contributes to the increase in number of the more severe cases of nephrogestosis.

Anoxemia from many causes is responsible for 18.5 per cent of all deaths in newborn babies. It is the fourth most frequent cause of death in this age group. Among the most frequent contributing factors of anoxemia are the age and parity of the mother, duration of labor, type of delivery, prepartal analgesia, and the anesthetics used during delivery. Less frequently, prematurity, premature separation of the placenta, bleeding placenta previa, or a short cord, prolapse, torsion, knot, kink, or compression of the cord may cause it. Anoxemia prolonged more than 2 minutes after delivery will cause cerebral changes, but the prompt initiation and maintenance of respiration within 30 seconds after the cord is cut will prevent these changes, and if respiration is established before 2 minutes it may oxygenate the blood sufficiently to arrest any changes which have begun.

GENITOURINARY SURGERY

ADRENAL, KIDNEY, AND URETER

Farneti, F.: Tuberculosis of the Renal Pyramids (Contributo allo studio della tubercolosi delle papille renali). *Arch. ital. urol.*, 1945, 21: 201.

Tuberculosis of the renal pyramids may be subdivided into the following classes: (1) miliary diffuse, (2) miliary circumscribed, (3) nodular, (4) cystic, and (5) ulcerocaseous.

The spread of the tubercle bacillus to the kidney may be hematogenous, through ascending urogenital infection, by way of the lymphatics, or by a combination of these methods. Hematogenous spread may be direct, as the apex of the pyramids is a vascular net which forms a delicate reticulum of capillaries stopping the tubercle bacilli at this point, or it may be indirect, the bacilli passing through the glomerulus with the urine and thus infecting the pyramids.

A typical case presents the following symptoms: pyuria, hematuria, dysuria, nocturnal polyuria, spontaneous attacks of pain in the lumbar region, and lumbar tenderness.

Recovery of the tubercle bacilli by ureteral catheterization makes an absolute diagnosis although the history of tuberculosis elsewhere in the body is of some help, and in some cases an exploratory kidney operation is necessary to reveal the tuberculosis on sect on.

Early nephrectomy is the treatment of choice provided the other kidney has good function. Prolonging the treatment causes the lesion to become diffuse and spread to the opposite kidney.

ARTHUR C. CIROLLA, M.D.

Deming, C. L.: The Prognosis and Problems in Renal Tumors. *J. Urol.*, Balt., 1946, 55: 571.

During the past 23 years, 82 cases of renal neoplasm have been admitted to the New Haven Hospital in New Haven, Connecticut. In the present report, these cases are carefully analyzed, and the methods of therapy evaluated.

Renal new growths were found to occur during two periods of life, the first decade and the latter decades. In the author's series 13.4 per cent of the tumors were found in children and this, along with the embryonic tumors in adult life, would seem to suggest a congenital factor. The absence of these tumors during adolescence, their scarcity during the third and fourth decades, and their preponderance in the male all are observations, but unexplained.

The cytological classification of tumors is referred to, but is viewed from the aspect of the clinician, and it is noted that irrespective of the histological picture, their subjective and objective findings are similar, as well as their prognosis. Present day therapeutics affords less than a 20 per cent chance of cure, and in this series only 9.08 per cent.

It is of interest to note in this series of cases that 11 occurred in children and only 3 of these were Wilms' tumors. The remaining tumors in this decade were sympathicoblastomas, sarcomas, embryonal carcinomas and neurogenic fibrosarcomas.

The author advocates repeated roentgenographic examinations to facilitate the diagnosis in questionable cases, but points out that usually pyelography quickly establishes the diagnosis of renal tumor by depicting a mass associated with the kidney, an abnormality or deformity of one or more of the calyces, or an abnormal peripheral outline of the suspected kidney. The author emphasizes the difficulty of surgical extirpation of a fixed kidney with tumor and suggests that the mobility of the organ be determined at the time of pyelography.

In this series of 82 patients with renal tumor, 60 had a nephrectomy, 4 had a biopsy of the tumor with ligation of the ureter, and 2 others had only a biopsy of the tumor. There were 4 operative deaths. Seven of the 82 individuals were admitted in extremis and died soon thereafter.

The mortality in the series of patients is presented graphically and reveals the results at a glance. In the group with hypernephromas, only 19.5 per cent of the patients were alive after 5 years; 14.6 per cent were alive after 10 years, but of these, only 9.08 per cent were free of tumor. The patients with sympathicoblastomas and embryonic carcinomas all died within 3 years. Tumors of the renal pelvis too were found problematical, and thus the author's final percentage of control was found to be 9.08 per cent for the group.

The unpredictability and multiplicity of metastatic lesions of renal new growths do not permit early removal of these lesions, and thus, control. Furthermore, irradiation has not proved to be effective since there is no means of absolute prediction of radiosensitivity. Thus, the only means of absolute cure is early diagnosis and complete surgical removal, but there is no means available to ascertain the presence or absence of minute widespread dissemination.

In addition it was found in this series of cases that there was little difference in the mortality of individuals whose condition was diagnosed and treated early, and in those in whom there was delay in diagnosis; i.e., 64 per cent and 58.7 per cent, respectively.

It is concluded from the finding of patients who died of the disease as late as 10 years following surgery, that a 10 year observation is not sufficient to assume a cure from renal malignancy, and that the present therapeutics which effects but a 9.08 per cent cure is far from satisfactory. The determination of malignancy and radiosensitivity by biological methods, in addition to the study of cytological architecture, is advocated along with the obvious fact

that the successful treatment of renal neoplasm is not found in the present methods at our disposal.

ROBERT LICH, JR., M.D.

Jacobs, A.: Transplantation of Duplicated Ureters Into the Bowel, with a Report on 3 Cases. *Brit. J. Urol.*, 1946, 18: 4.

A double ureter is comparatively common, and the possibility of the existence of such an anomaly must be borne in mind whenever the operation of transplanting the ureters into the bowel is contemplated. Among a series of 44 patients, on whom the author performed this operation, a complete double ureter was found in 3, all on the left side.

In 1 case of urethrovesicovaginal fistula the 3 ureters were transplanted simultaneously. In the second case (papillary carcinoma of the urinary bladder) the right ureter was transplanted at the first stage, and at the second stage, a month later, both left ureters were transplanted and total cystectomy with removal of the prostate and seminal vesicles was carried out. In the third case (infiltrating carcinoma of the urinary bladder) 2 dilated left ureters were implanted, and at the second stage, 1 month later, the right ureter was implanted and total cystectomy was performed.

In spite of the dilatation of the left ureters in the last case the implant took well and urine promptly appeared in the rectum, as determined by drainage from a rectal tube. The quick immediate recovery was soon followed by rapid deterioration and death due to generalized metastases.

The technique employed in all 3 cases was essentially that of the Coffey No. 1 operation. The author recommends the temporary presence of a ureteral catheter while the serosal and muscular flaps are being approximated to prevent constriction. The catheter is then withdrawn before the distal end of the ureteral stump is inserted into the lumen of the bowel.

FREDERICK R. LIEBERTHAL, M.D.

BLADDER, URETHRA, AND PENIS

Michels, L. M.: Wounds of the Urinary Bladder. *Ann. Surg.*, 1946, 123: 999.

In a 16 month period an auxiliary surgical group functioning in the Italian, French, and German theaters of war operated upon 3,154 wounded individuals; 155 of these (4.9 per cent) had bladder lesions. The diagnosis of a bladder lesion may be made from the alignment of the wounds of entrance and exit and by the location of the foreign body as demonstrated roentgenographically. The most frequent wounds of entry were in the buttocks (56 times) and in the anterior abdominal wall (56 times). Other sites of entry were in the hip, thigh, perineum, back, and flank. Wounds of exit were present in one-third of the cases, the missile having been retained in two-thirds.

There is nothing characteristic in the abdominal physical findings. The presence of a urinary fistula indicates damage to some portion of the genito-

urinary tract, as does hematuria. Clear urine does not contraindicate bladder damage (5 cases in this series). Filling of the urinary bladder with some solution prior to surgery for diagnosis is not recommended because of the danger of forcing contaminated material into the peritoneal cavity or retroperitoneal region. Since celiotomy is usually necessary for associated abdominal lesions, intraparietal bladder lesions can be seen directly.

The correct diagnosis was made preoperatively or at surgery in 149 of these cases. Six cases were overlooked, and 2 of the patients died. In 3 urinary fistulas developed, which later responded satisfactorily to cystostomy. The sixth patient passed a foreign body per urethra and recovered following the insertion of an indwelling catheter. Eighty-six per cent of the patients had bowel lesions in addition to the bladder damage. The former always receive primary consideration.

The mortality rate of patients having bladder lesions depends mainly upon how much bowel damage coexists. Uncomplicated bladder lacerations which are operated upon promptly are not life-threatening.

In 35 cases the injury was due to a bullet from a gun (mortality 34 per cent), in 71 to shell fragments (mortality 32 per cent), and in 9 to pressure (no mortality); in 46 cases the missile was not recorded.

In 137 cases the laceration was intraperitoneal, in 9 extraperitoneal, and in 9, both. Nine patients had a severe contusion without a laceration.

Repair of the laceration with suprapubic cystostomy is the surgical procedure of choice. The abdomen is opened to explore and repair whatever other intraperitoneal injury is present and the bladder injury is inspected and repaired at the same time.

No infection of the paravesical tissue occurred in any of the surviving patients.

FREDERICK R. LIEBERTHAL, M.D.

Milner, W. A.: The Treatment of Carcinoma of the Bladder for the Past 5 Years, with Special Reference to the Closed Method of Treatment. *J. Urol.*, Balt., 1946, 55: 607.

There are reported 245 cases which were operated upon for a vesical neoplasm during a 5 year period at the Albany Hospital in Albany, New York. The average age of the patients was 62.9 years, and the incidence in the male was found to be almost 3 times that in the female. The author notes with interest that 12.5 months elapsed after the initial symptom before the patient sought either diagnosis or treatment. Intermittent hematuria was the presenting symptom in 94 per cent of the individuals, and the remaining patients complained of dysuria or presented the neoplasm as an incidental finding during a cystoscopic examination undertaken for other reasons. In some the cystogram during intravenous pyelography presented the diagnostic filling defect of the bladder.

In 229 instances, or 93 per cent of the individuals, the closed method, or transurethral resection, was undertaken and the resection was carried to a depth

to expose the vesical musculature whenever neoplastic infiltration did not preclude this objective. In addition, it was advised that $\frac{3}{4}$ of an inch of normal mucosa around the base of the tumor be removed and that this be followed by thorough fulguration of the base. The author emphasizes the fact that tumor size is not a determining factor in the use of transurethral resection in the treatment, and to substantiate this contention 3 cases are reported in which the resected tumor weighed more than 100 gm. One tumor, weighing 344 gm., was removed in two sittings; the second, weighing 132 gm., was resected in a single sitting; and the third, weighing 127 gm., was removed in 2 operations, like the first. The first of these 3 patients was relieved of his obstruction for 12 months following the surgery, and the 2 others are living and free of their disease for 3 years and 7 months, respectively.

In addition to resection and fulguration, the use of radon seeds and deep x-rays is advocated. Platinum nonremovable seeds of 1.5 mc. are implanted so that each seed radiates an area of 1 sq. cm. The selection of cases for radium implantation is based on the evidence of infiltration at the initial cystoscopy. The x-rays, of from 4,000 to 5,000 units, are delivered through 3 portals and are used in individuals in whom extension of the condition is believed to require additional therapeutic assistance. Also, the author believes that x-rays materially reduce the rate of recurrence in multiple papillary carcinoma of grade I.

Fifteen patients were treated with partial cystectomy or segmental resection of the bladder. One of the patients in this group was operated upon on 2 occasions and at the time of this report had survived for 4 years and showed metastatic lesions. Another died as a result of the surgery. Four patients died of their disease, and the remaining 9 were alive and well from 2 months to 5 years after operation. Five of the 9 patients mentioned have had small recurrences which were controlled by transurethral fulguration or resection.

In 3 instances total cystectomy was done and the patients lived from 12 months to 2 years. The indication for this procedure was intractable pain in 1 case and multiple papillary tumors in 2 cases.

In reviewing the pathology of the tumors removed it was found that of the 240 tumors graded the majority were papillary carcinomas of grades I and II and next in frequency were epidermoids of grades III, II, and IV, respectively.

It is noted that the mortality figures revealed that the majority of the patients died less than 2 years after surgery, and that of the entire group of 189 patients, 77 died. Ten individuals died of other causes and were free of tumor at the time of death; 2 were moribund and died without having an operation, and 59, or 32.2 per cent, died as a result of their disease. The operative mortality in total cystectomy was 33.3 per cent as compared to 6.6 per cent in segmental resection and 0.44 per cent in transurethral resection.

Of the living individuals the majority have survived operation less than 2 years, and 4 for 5 years. One of the latter is at present suffering with the disease; this individual had been treated by segmental resection of the bladder.

The author concludes that transurethral resection of bladder tumors is to be reserved for vesical neoplasms of the less invasive type, but should be executed with a distinctly radical approach. In instances of increased neoplastic invasion the more frequent use of segmental resection and complete cystectomy is to be seriously considered.

ROBERT LICH, JR., M.D.

Vajano, D.: The Treatment of Cancer of the Penis (Il trattamento del cancro del pene). *Tumori*, Milano, 1942, 28: 55.

Of all the tumors of epithelial origin, carcinoma of the penis is the rarest, being present in only 20 of 2,194 cases. Although most of the patients were in the 6th decade, the youngest one was 26 years of age, and the oldest was 82 years of age. Predisposing factors in order of frequency are: (1) phimosis, (2) balanitis, (3) syphilis, (4) chancroid, (5) leucoplakia, (6) hyperplasia, (7) Paget's disease, (8) Bowen's disease, (9) trauma, and (10) venereal warts.

The pathological findings are grossly classified into two forms: a papillary tumor of the glans or an infiltrative tumor of the prepuce, and, histologically, a spinocellular epithelioma or a basal cell carcinoma.

The symptoms are pain in the glans and purulent discharge from the urethral orifice, which may be mixed with blood.

Metastases are rare and, if present, are slowly carried through the lymphatics to the inguinal lymph nodes.

The treatment may be one of three types: (1) surgery, (2) radiation, and (3) a combination of surgery and radiation.

Surgical management may be as follows: (a) excision of the primary lesion with the electrocautery, which is indicated early when no lymphadenopathy is present; (b) partial amputation of the shaft of the penis with the electrocautery, which is indicated in carcinoma of the glans; (c) amputation of the entire shaft (Gould's operation), indicated in disseminated carcinoma of the corpus cavernosum and spongiosum; (d) total emasculation (Chalot's operation), reserved in cases in which the scrotum is invaded, and (e) extirpation of the inguinal glands in conjunction with the operation of Gould or Chalot, indicated in cases that have been subjected to previous surgery or radiation therapy.

In radiation therapy, radium is used on the initial lesion, while in the more advanced cases x-rays are used on the lesion and the inguinal lymph glands.

The mixed method of treatment may be as follows: (a) amputation and irradiation of the glands with x-rays or radium; (b) radium or x-ray treatment of the primary lesion and removal of the inguinal glands; (c) radium or x-ray treatment of the primary lesion and removal of the inguinal glands, followed

by postoperative radiation to the glandular area; (d) radiation of the primary lesion plus conservative amputation and radiation of the lymph glands, with or without extirpation; (e) circumcision and radiation of the primary lesion with radium, and (f) electroresection of the primary lesion followed by radium therapy.

ARTHUR F. CIPOLLA, M.D.

GENITAL ORGANS

Wattenberg, C. A.: Liver Changes and Other Effects of Diethylstilbestrol during Treatment of Prostate Gland Cancer. *J. Urol.*, Balt., 1946, 55: 631.

The toxicology of synthetic estrogens with reference to experimental animals is briefly discussed and a case is reported of an individual who developed hepatitis during diethylstilbestrol therapy for malignancy of the prostate.

The patient was white, and 63 years of age. There was present irregularity of the prostate suggesting carcinoma, but no evidence of metastasis. The patient was placed on 15 mgm. of diethylstilbestrol daily until 150 mgm. had been taken, and thereafter the dose was reduced to 10 mgm. a day for a period of several months until a total dosage of 1,940 mgm. were consumed. At this time there was no ankle edema, very little breast enlargement, and no tenderness or pain. In addition, the patient's initial nocturia of 6 times, frequency, inability or difficulty in initiating the urinary stream, and dribbling all had subsided. He felt himself in excellent health. The daily dose of diethylstilbestrol was reduced to 5 mgm. and after more than 620 mgm. had been used at this dosage, or a total of 2,700 mgm., the patient began complaining of gastric distress and a constant feeling of hunger in spite of eating regularly. This was followed by a dermatitis which was diagnosed as a "drug rash." Icterus soon followed and along with it, leg and ankle edema, enlargement and tenderness of the liver, and a prominence of the superficial abdominal veins. The icterus index was 200 and better x-ray examination of the bony pelvis revealed metastases although the prostate at this time felt small and soft.

At the time of an exploratory laparotomy the liver was found smooth and without tumor. A biopsy showed fibrosis of the portal areas, and surrounding the central veins the bile capillaries were dilated. There was evidence of bile retention and cloudy swelling—a toxic hepatitis. The gall bladder and common duct were dilated but this was found upon histological study to be due to edema, and a similar picture was found in the pancreas and a regional lymph node.

After several months of not taking diethylstilbestrol, the patient noticed the onset of urinary complaints. Since the resumption of the synthetic hormone was thought contraindicated in this case, a bilateral orchiectomy was done.

The author briefly mentions the side effects of diethylstilbestrol when it is given for carcinoma of the

prostate. The cytological effects in the prostatic cancer are regression of the previously foamylike cytoplasm, eccentricity of the nuclei, along with pyknosis, and even actual destruction leaving only cytoplasmic debris. In the testicle the effects are a thickening of the basement membrane of the seminiferous tubules with fibrous tissue and marked arrestment of spermatogenesis. The posterior urethra reveals squamous metaplasia. The breasts reveal edema, proliferation of the duct epithelium along with budding of the ducts, an increase in both connective tissue, and vascularity and a deposition of fat.

The article is well illustrated with exceptionally clear cut microphotographs of tissues in both the pre- and postdiethylstilbestrol phase.

ROBERT LICH, JR., M.D.

Sworn, B. R., Marshall, F. W., and Edwards, J. L.: Solid Tumors of the Epididymis. *Brit. J. Surg.*, 1946, 33: 375.

Tumors of the epididymis are still regarded as rare. However, in 5 years the authors have seen 3 such tumors of glandular type, 2 of which are described in detail. Each had a fibrous capsule containing smooth muscle in varying amount in addition to the glandular elements. Lymph follicles with germinal centers were also present. The morphology of the cells lining the tubules provided inconclusive evidence as to whether the growth was an endothelioma (or mesothelioma as suggested by Mackay) on the one hand, or an adenoma on the other.

Since glandular elements, plain muscle, and lymphoid tissue with germinal centers are associated in many of these tumors, and since their origin is still debated, the authors believe that the least objectionable and most noncommittal designation would be "mixed tumors" of the epididymis. As in the case of the salivary glands, the term is held not to possess the implications of teratoma.

These tumors appear to be benign and the history often covers many years, but the postoperative period is in most cases not yet long enough to be significant.

FREDERICK R. LIEBERTHAL, M.D.

Scheetz, R. J., and Leddy, E. T.: Roentgen Therapy for Malignant Teratoma of the Testis. *Am. J. Roentg.*, 1946, 55: 754.

This article is based on 54 cases of malignant teratoma of the testis that have been observed at the Mayo Clinic.

Since these tumors usually develop during the period of greatest sexual potency, it has been thought that there possibly is some relation between sexual function and the development of the tumor. A history of trauma can be obtained in from 10 to 30 per cent of the cases of teratoma but it is doubtful whether trauma has any etiologic significance. It does, however, serve to call attention to a pre-existing malignant lesion.

It is generally accepted that cryptorchidism tends to favor the development of malignant tumors of the

testis. In all of the cases in this series, the involved testis was situated in the scrotum. In the series of 54 cases of teratoma, the youngest patient was 15 years of age and the oldest was 59 years. In more than half of the cases (54 per cent) the patients were in the third decade of life and in 50 cases (93 per cent) the patients were between 15 and 39 years of age.

Broders divided tumors of the seminal epithelium into three main groups: (1) teratomas, (2) adenocarcinomas of the seminoma type, and (3) adenocarcinomas of the testis. The teratomas were subdivided into two subgroups: the benign and the malignant.

In this series of 54 cases, the site of the tumor was in the right testis in 28 cases and in the left testis in 26 cases.

A painless swelling of the testis was the initial symptom in 68 per cent of the 54 cases.

The tumor may be very small and be buried in the substance of the testis; on the other hand, the involved testis may be as large as a fetal head. In 13 of the 37 cases in which the tumor had not been treated previously, the involved testis was the size of an orange when the patient was examined.

In 7 cases the initial symptoms were referable to the metastatic lesions. This would seem to indicate that malignant teratomas tend to metastasize early, often before the patient is aware that the testis is the seat of serious trouble.

A painful testis was the only symptom in 3 cases, in 5 other cases pain was associated with swelling of the testis. In 8 additional cases, the patients complained of a painful testis when they sought medical advice, therefore, testicular pain was a prominent symptom in 16 cases. Pain occurs more frequently in cases of malignant teratoma than it does in cases of seminoma.

Many other symptoms were present by the time the patients consulted a physician. One of the commonest symptoms was dragging pain in the groin on the involved side, and this often was accompanied by pain in the lower part of the back.

In 17 of the 37 cases in which the tumor had not been treated previously, there was clinical evidence of metastasis when the patients were examined. The site of the metastatic lesions in these cases was: the para-aortic lymph nodes in 13 cases, the supraclavicular lymph nodes in 7 cases, the peribronchial lymph nodes in 6 cases, the inguinal lymph nodes in 5 cases, and the bones in 1 case.

In 5 cases the breasts were enlarged and tender. This change is due to an actual proliferation of the mammary tissue which apparently is stimulated by gonadotropic substances in the primary tumor or in the metastatic lesions.

A hydrocele was present in 7 of the 37 cases. A varicocele was present in 2 cases.

A few of the diseases that may be confused with a tumor of the testis are tuberculous epididymitis, hydrocele, hernia, gumma of the testis, and hematocele. The finding of a firm, smooth or nodular scrotal

mass that is about the same shape as a normal testis and does not involve the epididymis should cause one to suspect that a tumor of the testis is present.

The value of the tests for gonadotropin is decidedly limited for the following reasons:

1. From the diagnostic standpoint, one cannot confidently predict the histopathological type of testicular tumor on the basis of either the quantitative or qualitative determination of gonadotropin in the urine.

2. From the prognostic viewpoint, one cannot exclude metastasis because an excessive amount of gonadotropin is not determined in the urine.

3. The test is too expensive and complex to be used elsewhere than in large institutions.

In cases of tumor of the testis observed at the Clinic treatment usually consists of simple orchectomy followed by roentgen therapy. The treatment, of course, is modified to fit the needs of the patient.

Leddy and Desjardins, and Nash and Leddy have described the technique of roentgen therapy of tumors of the testis.

The proponents of preoperative roentgen therapy claim that operation may cause metastasis and that preoperative roentgen therapy may seal off the lymphatics and prevent metastasis. The opponents of preoperative roentgen therapy maintain that orchectomy will not cause metastasis if the spermatic cord is clamped at the external inguinal ring, and that it will effect a cure if metastasis has not occurred before the operation is performed.

The most convincing argument in favor of preoperative roentgen therapy is that it apparently has a tendency to increase the percentage of patients who live for 5 years after operation.

That an agmatous or a tuberculous testis has on occasion been irradiated as a result of a mistaken diagnosis of tumor is within the realm of possibility. In cases in which there is no evidence of metastatic lesions and in which the amount of gonadotropic hormone in the urine is within normal limits, one might never be certain of the diagnosis after preoperative irradiation.

Within a short period after roentgen therapy first was used in cases of tumor of the testis, it became obvious to many observers that true malignant teratomas are much less susceptible to the action of roentgen rays than are seminomas.

In the analysis of the results of roentgen therapy, 18 of the 54 cases were excluded for various reasons. The remaining 36 cases were divided into three groups: group 1 included 17 cases in which treatment was begun before there was any evidence of metastasis; group 2 included 11 cases in which there was clinical evidence of metastasis when treatment was begun, and group 3 included 8 cases in which the patients had undergone orchectomy before they came to the Clinic. In all of the cases in the last group, clinical evidence of metastasis was present when the patients were first observed at the clinic.

Group 1. In this group of cases the prognosis obviously should be considered favorable. Treatment

consisted of simple orchiectomy and postoperative roentgen therapy. Only 8 of the patients in this group were alive 5 years after orchiectomy was performed, but 1 patient died of meningitis after mastoidectomy which was performed 55 months after orchiectomy. The average period of survival of the patients who died was 19 months.

Group 2. In this group, the results were very discouraging. Only 1 of the 11 patients in this group lived more than a year after orchiectomy. This patient lived 16 months after the operation.

Group 3. In a few of the cases in this group, roentgen therapy had been employed before the patients came to the Clinic. Radium therapy had been employed in 2 cases. In some respects, this group is a composite of groups 1 and 2 as some of the patients undoubtedly had undergone orchiectomy before clinical evidence of metastasis had become manifest. The average period of survival after orchiectomy was 17 months.

JOHN A. LOEF, M.D.

MISCELLANEOUS

Winsbury-White, H. P.: Some Observations on the Incidence of 665 Personal Cases of Urinary Lithiasis. *Brit. J. Urol.*, 1946, 18: 13.

The author calls attention to the fact that certain easily distinguishable factors have controlled the incidence of urinary lithiasis, as demonstrated by a study of the literature of the past century. Vesical calculus was much more common than renal calculus until the beginning of the present century. The correction of bladder neck obstructions in the adult and the improvement of the diet of children, especially of the working classes, with the greater use of milk with its vitamin A and readily absorbable calcium, have led to a sharp reduction in the incidence of vesical calculus. Renal calculus has definitely been on the increase, especially in Central Europe, where from 1924 to 1937 an obvious "stone wave" has occurred.

Renal calculi are more common in the male and tend to favor the left side. The male internal genital organs are more intimately related to the urinary tract and hence infective processes occurring in them and obstructions resulting from them would tend to encourage pathological processes in the kidney more in the male than in the female. The relative incidence of stone in the urinary tract increases in the male sex as compared with the female as we descend, as follows: only a slight predominance in the kidney, more than 2 to 1 in the ureter, and more than 6 to 1 in the bladder.

Residual urine in the bladder is far more common in the male, and, when present, may in itself be an adequate explanation even with regard to the upper urinary tract.

Lithiasis tends to be multiple in the urinary tract, especially if untreated. In 51 per cent of the author's cases of renal calculus, the stones in the kidney were multiple and in 14 per cent they were bilateral.

Prostatic calculi commonly have the same chemical composition as renal calculi, and they are often associated with calculi elsewhere in the urinary tract.

FREDERICK R. LIEBERTHAL, M.D.

Begg, R. C.: Some Uses for Free Muscle Grafts in Urology. *Brit. J. Urol.*, 1946, 18: 10.

The author recommends the use of free grafts taken from the oblique abdominal muscles, the recti, pyramidales, or elsewhere in various urological procedures.

Effective hemostasis is accomplished when such grafts are used in the repair of operative wounds of the kidney substance after nephrotomy and partial resection, and for the control of bleeding of extrapelvic vessels. Incisions in the ureter, pelvis, or bladder may be effectively sealed, and postoperative leakage is prevented. In vesicovaginal and rectourethral fistulas a pad of muscle will form an effective buttress between the suture lines.

FREDERICK R. LIEBERTHAL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Agerholm, M., and Trueta, J.: *Acute Hematogenous Osteomyelitis Treated with Penicillin*. *Lancet*, Lond., 1946, 1, 877.

Two well defined groups of cases of acute hematogenous osteomyelitis were distinguished: (1) those admitted before the bone was seriously damaged and pus had been formed, and (2) those admitted with an abscess already present.

The authors propose the following conception of the disease process as a useful working basis. At the earliest stage there is a small focus of infection in the bone, probably with a septicemia. If the organism is penicillin sensitive, penicillin given at this stage will control the septicemia and limit the focus to an area small enough for resolution to occur. The presence or absence of roentgenographic changes depends on the size of the affected area and its position. If, however, the penicillin is not given at the early stage, the local infection will spread. The infection next reaches the periosteum. This provides a resistant barrier to penetration but is readily stripped up from the bone, and the pus, which is under considerable tension, may spread subperiosteally along the length and circumference of the shaft, causing further interference with the blood supply. If penicillin is given at this stage the general infection may be overcome, but the pus both within and without the bone, unless drained, remains as a twofold danger.

The following general principles and routine of treatment were advocated: (1) hematogenous osteomyelitis is in part a systemic disease and therefore penicillin must be given systemically; (2) systemic administration of penicillin alone can cure the disease provided that (a) there is no abscess at the focus, is continued long enough; (3) systemic administration of penicillin cannot sterilize an abscess, therefore cases in which an abscess is already present the systemic infection may be controlled, but even after clinical recovery the disease in the bone may progress and lead to extensive destruction of the bone (surgical removal of preformed pus is essential in this disease as in other infections susceptible to penicillin); and (4) after the removal of pus, systemic administration of penicillin can prevent the further formation of pus, and therefore primary suture is safe. In view of the danger of secondary infection in bone, primary suture is a valuable protection.

The penicillin was given intramuscularly either by drip or by intermittent injection. Intramuscular drips have been used whenever possible. They are used for children by the nursing staff. The E.M.S. penicillin drip set is used; 100 c.c. of saline solution is used to dissolve the 24 hour dose, a maximum of

400,000 units a day. This occasionally caused local cellulitis, and three patients developed "penicillin" abscesses containing sterile pus; all subsided after one aspiration.

Thirty cases of acute osteomyelitis were treated with penicillin in 18 months. Blood culture was positive in 14 of these cases. Penicillin was used alone in 9 cases; 2 of these were early cases and would now be treated surgically. Seven of 30 cases (about 1 in 4) were suitable for penicillin treatment alone. Primary suture was combined with surgery in 21 cases. Penicillin was done in 14 cases and secondary suture in 5 cases; 2 cases were not sutured. All cases operated upon were suitable for primary suture, but this was not realized at first.

In this series there was no death, no joint involvement, and no secondary focus after admission. At the end of 18 months, 4 cases still presented a sinus, but 2 of these were nearly healed; 28 patients had normal function; 1 patient admitted with septic arthritis of the knee had a limited range of movement; 1 had a sinus which kept her in the hospital.

C. FRED GOERING, M.D.

Oleaga Alareon, F.: *First Results in the Treatment of Osteomyelitis with Penicillin* (Primeros resultados en el tratamiento de la osteomielitis con penicilina). *Rev. orlop. traumat.*, B. Air., 1945, 15: 61.

The author reports the findings in 11 cases of non-tuberculous osteomyelitis in single bones treated with penicillin. He found that the acute osteomyelitis is evidently influenced favorably by the penicillin treatment. In general there was rapid disappearance of the symptoms, but persistence of the roentgenological findings. The bacteria were stabilized or killed, but the tissue inflammation continued its course. The penicillin was found to be preferable to sulfas drugs in these cases because of the lack of toxicity.

In cases with osteomyelitis rest and immobilization are indicated in addition to the chemotherapy. Chronic osteomyelitis with sequestra should be operated upon.

The author thinks that penicillin treatment should be used in compound fractures in order to prevent chronic inflammation of the bone.

WILLIAM E. RICKETS, M.D.

Pollidori, A.: *Roentgenological Appearance, Early and Late, of Congenital Proluxation of the Hip Treated with Abduction Splints* (Aspetti radiografici precoci e a distanza della prelussazione congenita dell'anca trattata con l'abduzione sul cuscino deviatricore). *Chir. org. movim.*, 1943, 29: 116.

Seven hundred and seventy-seven cases of dislocation of the hip were treated at the Istituto Rizzoli from 1921 to 1937, by early application of abduction splints. Of these, 478 were available for subsequent re-examination. According to the classification of

Putti, a grade of 9 or 10, corresponding to good or excellent, was given to the results in 93.9 per cent of the cases. In 21 instances, an osteochondritic process was found involving the epiphysis or the growth center. These cases were again examined and evaluated, the time interval since treatment varying from 2 to 13 years.

The cases fell into two groups: (1) those with osteochondritis of the epiphysis, and (2) those in which rarefaction was limited to the epiphyseal line. In the first group it was noted that, even when the dislocation was frankly unilateral, completely normal conditions were never found on the other side. This fact conformed to the impression that neonatal dysplasia of the hip is always bilateral, as is also dystrophy; but since these findings are not confirmed by roentgenological studies in individuals older than 12 years, on the average, it is assumed that in many cases dysplasia and dystrophy are slight and may clear up spontaneously. On the affected side, it was found that there was either marked hypoplasia or a notable delay in the appearance of the epiphyseal growth center, in all cases. Such osteochondritic changes appeared early in the period of treatment.

In the second group the inferior portion of the femoral neck, close to the growth cartilage, showed changes resulting in failure of growth of that part and the characteristic deformity of coxa vara. In several cases the changes were limited to the inferior pole of the epiphysis.

Having described the small group of failures resulting from the prompt use of abduction splints, the author discusses the nature and pathogenesis of morbid processes associated with congenital preluxation treated by any method. The possible factors of trauma from manipulation, osteochondritis, and osteoarthritis are discussed, the latter two being in turn influenced by constitutional, vascular, or humoral factors. The frequently associated absence of the round ligament is cited, and the hypothesis is proposed that vascular alterations or lability could well be superimposed upon congenital dystrophy and dysplasia to bring about the described deformity.

Survey of long term results indicated that cases which became worse with age were those with associated osteoarthritis, a situation almost never found in cases treated very early. It is suggested that the virtue of treatment by abduction splints depends less upon the avoidance of surgery than upon the early timing of its institution.

EDITH B. FARNSWORTH, M.D.

Pacini, D., and Rizzi, C.: A Contribution to the Anatomic Study of the Round Ligament of the Femur (Contributo allo studio anatomico del legamento rotondo del femore). *Chir. org. movim.*, 1943, 29: 196.

The present studies are based upon the gross and histological examinations of 150 round ligaments, of which 40 were taken from fetuses in various stages of intrauterine life. In addition, arteriograms were made in 6 cases by the injection of the iliac artery.

The following observations and conclusions were made:

1. The round ligament is found to act as a vector for blood vessels to the epiphysis of the femur from 4½ months of intrauterine life up to old age.

2. Arteries of injectable caliber never exceed 2 in number.

3. In the fetus and the infant these vessels supply only the region of the fovea, whereas in later life they are seen to participate in the circle of the circumflexes.

4. Throughout the years of growth and adulthood, the artery of the round ligament is found to enlarge and penetrate the spongy bone.

5. A mechanical function subserved by the round ligament is highly questionable.

On the basis of these observations which were made in addition to microscopic studies of the ligaments and vessels, it is to be concluded that the role of the round ligament in diseases of the hip joint has been overestimated, whereas in fractures of the neck of the femur it is probably of prime importance.

EDITH B. FARNSWORTH, M.D.

Bonnin, J. G.: Osteochondritis Dissecans and Torn Lateral Meniscus. *Brit. J. Surg.*, 1946, 33: 380.

The association of osteochondritis dissecans with lesions of the menisci was found in 3 cases by Fairbank. The author notes that osteochondritis dissecans usually occurs on curved surfaces which are subjected to frictional strain, such as the superior articular surface of the femur, the upper surface of the talus, and the capitellum of the humerus.

In the case presented, the patient had a bucket handle lesion of the lateral meniscus with a history of repeated locking extending over a period of 7 months. At operation there was found a curved fissure in the external condyle of the femur overlying the osteochondritic fragment which had been visualized in the roentgenogram. The lateral meniscus was found to have a bucket handle tear, which was turned over and lying in the intercondylar notch.

The semilunar cartilage was removed. Fifteen ¼ inch drill holes were made through the depressed cartilaginous area into the condyle of the femur, and the joint was then closed. The limb was rested for a fortnight in bed and for 6 weeks thereafter in a plaster cast.

Ten weeks later, approximately 18 weeks after surgery, there was still a small effusion, but the patient had no complaints and could walk 4 miles.

DANIEL H. LEVINTHAL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Prigge, E. K.: The Treatment of Chronic Osteomyelitis by the Use of Muscle Transplant or Iliac Graft. *J. Bone Surg.*, 1946, 28: 576.

The author presents the method used in treating 64 separate foci of chronic osteomyelitis in 61 patients on the orthopedic service of the De Witt

Figs. 1, 2 and 3. Examples of muscle pedicles used in filling bone defects.

General Hospital, Auburn, California. Practically all areas of the skeleton were involved. Healing occurred in a high percentage of the cases within 10 weeks and there were no recurrences, pathological fractures, or fatalities. The average period of observation was 7½ months.

It has become apparent that penicillin, like the sulfonamides, given either systemically or locally, is not entirely effective in tissues with little or no vascularity. Such tissues include sinus tracts with surrounding cuff of dense scar tissue, bone abscesses, sequestra, and the area of eburnated bone which is frequently found at sites of chronic osteomyelitis.

It was known that in osteomyelitis of a rib or of the fibula, excision of that part of the bone containing the infection is almost invariably followed by prompt and complete healing, because of the fact that upon removal of the diseased bone the adjacent viable and vascular (and, therefore, infection resistant) muscles fold into the defect, obliterating the dead space. Therefore, it was believed advisable to treat bone infection wherever found in a similar way, that is, by excising all infected and hypovascular tissues, obliterating the dead space, and closing the wound.

Recently the obliteration of bone defects by exteriorization and the application of primary or early secondary skin grafts directly to the defects has again been recommended and good results are reported.

Two methods of obliterating the defects are described. The first is by the use of the viable muscle

pedicle as suggested by Starr and Mercer, and the second by the use of thin chips of cancellous bone obtained from the wing of the ilium.

The use of the muscle pedicle is the method of choice and can be used in such skeletal areas as the scapula, clavicle, humerus, forearm bones (except the radial styloid), and metacarpals in the upper extremity; the pelvis, femur, fibula, and metacarpals (and in selected instances the tibia) in the lower extremity; and the vertebral processes and ribs. In these areas the procedure was to excise the avascular and infected tissue radically, fill the bone defect with viable muscle, and do a loose primary or secondary suture even if this meant leaving the extremity flail, but clean surgically. Closure of the skin and superficial fascia over the wound should be done, even if it is necessary for the operator to make a relaxing incision on one or both sides of the original wound.

Methylene blue injected into the sinus tracts aids en bloc excision. The surgical approach always extends well into normal tissue, both proximal and distal to the diseased condition. This is essential, not only for complete visualization of the diseased tissue but for preservation of important nerves and vessels and for a proper selection of a portion of muscle to be sacrificed, if needed, by forming it into a pedicle which must be viable. All abnormal tissue—sinus tracts and infected granulation tissue, sequestra, eburnated and abnormal bone—and foreign bodies, if involved, were removed radically so that all remaining tissue appeared normal and had good vas-

Fig. 4. Shows two typical defects, before and after excision and iliac bone graft. A, Coronal section of a large defect and detail of "bricking-in" the iliac chips. B, Shows partial coronal section. C, Sketch of lateral view, showing the surface of the grafted area.

cularity. The bone defect, if shallow, was obliterated by slight displacement of the surrounding muscles; if deep, a muscle pedicle was formed and sutured into the defect. A direct or eccentrically placed drain was removed in 48 hours. Appropriate plaster cast immobilization was applied, as indicated. All of the patients received penicillin intramuscularly for 3 weeks.

Forty-four foci of infection in 42 patients were treated by this method. Good results were obtained in 43; there was 1 failure in which drainage persisted, the failure being due to incomplete removal of eburnated bone. The average period of drainage prior to operation was 20 weeks; after operation it was 3½ weeks. Twenty-one wounds were healed completely at the time of first inspection—usually from 10 to 15 days after operation.

Obliteration of the defect with an iliac graft was done when the anterior surface of the tibia, the radial styloid, and the calcaneus were covered only by integument, fascia, and ligamentous and tendinous structures, and muscle tissue was not available for a transplant.

The procedure in this second group, which accounted for 31 per cent of the cases in this series, was

complete excision of all infected and avascular tissue as in the first group. The bone defect was lightly filled with gauze dressings wrapped around either a Dakin tube or male catheter which extended through the gauze dressing and cast. Through this, from 2 to 4 c.c. of penicillin solution, containing 250 units per cubic centimeter, were instilled 4 times during the 24 hours, and 25,000 units were administered intramuscularly every 3 hours. After from 7 to 10 days, according to the size of the defect, the wound was inspected and the defect was always found to be covered with a thin layer of healthy granulation tissue.

A second operation was performed the next day. The appropriate iliac crest was prepared in the usual manner and small cancellous chips, approximately 4 cm. long, 1 cm. wide, and 3 cm. thick, were removed and the cortical bone was discarded. The iliac wound was closed before the recipient site was exposed, in order to prevent any cross contamination. The granulating defect was thoroughly and gently irrigated with from 1 to 2 liters of normal saline solution, and the surrounding skin was prepared with ether, alcohol, and merthiolate, care being taken to get none in the recipient site. The grafts were then "shingled" or "bricked" into place so as

to fill the defect. The wound was closed, except for a small opening or vent directly over the grafts, which was maintained by a vaseline gauze wick, and the part was immobilized in plaster.

In from 3 to 6 weeks the wound was ready for secondary closure with a relaxing incision, pinch grafts, or a pedicled graft when necessary. There were 3 criteria for timing secondary or plastic closure: (1) no sinus tracts may be present; (2) healthy granulations must cover all of the graft and the recipient bone; and (3) the surrounding soft tissues must not be edematous or inflamed.

Twenty cases of chronic osteomyelitis were treated with grafts of iliac bone. Complete healing occurred within 10 weeks; in 8 cases healing required a longer period. Failure occurred in 4 cases.

VERNON C. TURNER, M.D.

Pack, G. T., and Ehrlich, H. E.: Exarticulation of the Lower Extremities for Malignant Tumors. *Ann. Surg.*, 1946, 123, 124: 965, 1.

Sacroiliac disarticulation or hemipelvectomy has been performed 132 times during the last 50 years. Billroth, Trendelenburg, McBurney, Wyeth, Senn, Halsted, and Braehar of Kentucky (1866) were among some of the early master surgeons who attacked this formidable operation.

The present report is comprised of 25 cases of hip joint disarticulation. Five of these were combined with deep iliac dissection, and 6 amputations were made through the sacroiliac joint (hemipelvectomy).

The indications are as follows:

1. Large malignant tumors of the soft somatic tissues of the middle and upper thigh which cannot be adequately extirpated by thigh disarticulation.
2. Malignant osseous and periosteal tumors, involving the upper end of the femur and traversing the acetabular structures.
3. Fungating ulcerated neoplasms affecting the upper thigh, buttocks, groin, and hemilateral intrapelvic tumors (these may require sacroiliac disarticulation).
4. An infected neoplastic process, such as Kaposi's hemorrhagic sarcoma.
5. Massive osteochondroma of the innominate bone, and massive plexiform neurofibroma of the upper thigh and buttocks.

In this series of 25 hip disarticulations performed by the authors, 7 were done for spindle cell sarcoma, 4 for neurogenic sarcoma, 3 each for synovium, chondrosarcoma, and melanoma, 2 for endothelial myeloma, and 1 each for rhabdomyosarcoma, reticulum cell sarcoma, and liposarcoma. Five of the operations were performed for palliation.

The preoperative considerations include correction of the electrolyte derangement, i. e., anemia, dehydration, hypoproteinemia. Elastic bandage was not recommended except in cases of melanoma when it might avert dissemination of the tumor cells into the blood stream. Antiseptic sprays and dressings, débridement of infected and necrotic tissue, and daily surgical cleansing of the vagina may enhance

early healing and prevent wound contamination. Colonic irrigation and catheterization before surgery is also advised.

The anal orifice is closed with a pursestring suture, and the scrotum in the male is sutured to the opposite thigh. The incision runs from the pubic tubercle, extending upward and outward, to a point beyond the iliac crest. The posterior incision courses above the greater trochanter and along the infraglenal fold to the perineum, joining the anterior incision at the superior border of the symphysis pubis. The rectus abdominis is divided at its insertion and Poupart's ligament is severed at both ends. The abdominal wall is detached from its pelvic floor which is displaced upward. Care must be exercised in mobilizing the spermatic cord medially. Besides retracting the peritoneum, intestines, and bladder, one must identify the ureter and conserve its continuity. Double ligation of the external iliac vein is postponed until all the blood from the extremity has been returned to the vena cava. The pubic symphysis is exposed, skeletonized, and cut with a Gigli saw. After skeletonizing the crest, the iliopsoas muscles are severed together with the iliacus, pyriformis, gemelli, and levator ani muscles. Transection of these muscles results in the complete exposure of the sacroiliac joint. Disarticulation of this joint is accomplished during the anterior phase of the dissection. Bleeding resulting from severance of both synchondroses may be controlled by packing. At this juncture, the patient is turned on his unaffected side and the posterior dissection is terminated by dividing the gluteal muscles, sacral ligaments, lumbar nerve trunks, and gluteal and obturator arteries. The specimen is removed.

Vigorous and troublesome bleeding may be avoided by ligation of the common iliac artery, but because of certain obvious drawbacks the authors do not recommend it routinely. Ligation of the common iliac artery is alleged to cause retardation in the healing of the flap, necrosis, and secondary infection. The large nerve trunks are injected with alcohol and ligated.

The postoperative complications were: (1) abdominal distention, (2) paresis of the urinary bladder, (3) delayed wound healing due to necrosis of the muscle tags, lymphorrhea, and fat necrosis, (4) osteomyelitis (encountered once), (5) anemia, (6) hernia (none occurred in the authors' series despite the fact that the abdominal organs were held *in situ* by skin, fascia and peritoneum).

Six case reports of sacroiliac disarticulation follow. The first patient was 16 years old; disarticulation was performed for Kaposi's hemorrhagic sarcoma of the lower extremity. The second patient was 57 years old and was subjected to disarticulation for myxoliposarcoma of the buttocks. The third patient, aged 60, was operated on for chondrosarcoma of the pubis and ischium. The fourth patient, aged 15, was operated on for a neurogenic sarcoma of the thigh and pelvic parietes. The fifth patient, aged 45, was subjected to disarticulation for periosteal fibrosar-

B, The posterior flap is outlined by carrying the lateral termination of the anterior incision downward, coursing above the greater trochanter and along the infraglutal fold to the perineum. C, The anterior and posterior incisions are then joined at the superior border of the symphysis pubis. (Courtesy of J. B. Lippincott Co.)

coma of the ischium, and the last, aged 57, for extra-osseous osteogenic sarcoma of the groin and thigh.

The soft neoplasms had the best prognosis. They were neurogenic sarcoma and nonmetastasizing low-grade spindle cell sarcoma of the fascial tendon type. Of the tumors in hard tissue (bone), chondrosarcoma gave the most favorable prognosis.

One-third of all of the patients reported in the literature who have been hemipelvectomy for malignant neoplastic disease were reported to be clinically cured. Of the 6 cases reported an accurate prognosis cannot be ventured at this early postoperative period.

SAMUEL L. GOVERNALE, M.D.

Gherlinozoni, G.: The Retracted and the Short Amputation Stump of the Leg. Treatment and Prosthesis (Monconi flessi e monconi corte di gamba: trattamento e protes). *Chir. org. movim.*, 1943, 29: 37.

There were 214 cases (17 per cent) of persistent flexion at the knee joint in the author's material of 1,245 leg amputations. The more stubborn cases were those healing after prolonged periods of suppuration of the stump with extensive cicatrization of the surrounding tissues. The irreducible character of

the deformity is not so much the result of shortening of the ligaments and contraction of the capsule of the knee joint as of inflammatory infiltration or cicatricial changes in the muscles controlling the movements of the stump and knee joint. In the cases healing without suppuration, the flexed condition of the knee is likely to be corrected by physiotherapeutic measures. The flexed attitude of the knee is the natural resting or relaxed posture of the knee joint during the period of healing and might be avoided in the beginning by prophylactic bracing or splinting of the limb during the period of healing.

When the retraction has been allowed to become permanent and it resists correction by physiotherapeutic measures, operative procedures may be necessary. This is more likely to be the case when the amputation stump is short, and it is chiefly with the problem of the short stump that the author is concerned. Capsulotomy of the popliteal region of the articular capsule of the knee may be indicated; however it is not likely to succeed in the cases not correctable by physiotherapy without the addition of some type of lengthening operation on the muscles or muscle tendons, and this, together with the long postoperative period of corrective splint or cast bearing, is likely to

affect adversely the already diminished mobility of the knee joint.

In 5 of the more stubborn flexion deformities, therefore, a supracondylar osteotomy was done, and in a patient with marked osteoporosis the femur was broken manually and the bone allowed to heal with the stump in the extended position. The author thinks that this is the first time that osteotomy has been done for this condition.

The osteotomy consisted of an incision over the lateral aspect of the lower end of the femur, this bone being approached by blunt dissection between the vastus lateralis and the rectus anterior muscles. A wedge of bone is chiseled through the femur with the base of the wedge anterior, which guards against possible injury to the popliteal vessels and nerves. The limb is then immobilized in a cast for 2 months. In a patient in whom the amputation stump was so short as to be of no use, the idea of operation was rejected and the limb abandoned to the wearing of an end weightbearing prosthesis.

At the author's institution (*Istituto Rizzoli*, Bologna, Italy) the construction of the prosthetic apparatus for these patients has in general followed the lines laid down by Mommensen with the hinge 1 or 2 cm. above the fulcrum of the knee joint; however, some refinements have been added, including a leather cap for the stump which provides a snug fit of the stump in the leg section and a single bearing surface at the ischium. A cutout from a moving picture film shows the naturalness of the gait with this apparatus on the amputated patient. In all these short stump patients the classic operations for lengthening of the stump proved not to be necessary.

JOHN W. BRENNAN, M.D.

Fig. 1. The line of incision for the Syme amputation.

has many advantages over amputation through the foot, which is then too short for good function. Frequently there is muscle imbalance which permits an equinus deformity. The Syme amputation is the only amputation recommended at the ankle joint.

Unfortunately, the indications for the Syme amputation are restricted. Approximately 2 per cent of American Army amputees from World War II have had the Syme amputation. It requires greater skill on the part of the surgeon, with regard to the proper selection of cases, the operative technique, and the postoperative care than any other amputation. The bulbous ankle may be objectionable, particularly to young women.

The Syme amputation should not be performed after ligation of major vessels until sufficient time has elapsed for good collateral circulation to develop. It should not be done in the presence of sepsis, or in the presence of peripheral vascular diseases, such as thromboangiitis obliterans or arteriosclerosis; and it should not be done upon diabetic patients. Spina bifida and loss of sensation in the heel from injury or disease of the peripheral or central nervous system constitute clear cut contraindications.

Its greatest field of usefulness is in young men who are otherwise in good physical and mental condition but who have suffered the traumatic loss of the greater part of the foot. A good Syme amputation may be done if as much as 1 inch of good plantar skin is left on the heel. It may be performed for loss of the forefoot due to frostbite, trenchfoot, freezing, or any combination of these injuries, provided that sufficient time has elapsed for the local circulation to be re-established, and that persistent tenderness is not present in the soft tissue covering of the heel.

The extremity should be cleaner, surgically and bacteriologically, than for any other amputation. It

Aldredge, R. H., and Thompson, T. C.: The Technique of the Syme Amputation. *J. Bone Surg.*, 1946, 28: 415.

The merits of the Syme amputation, first described over 100 years ago, have been debated more than those of any other major amputation. It was employed rather extensively by the British and Canadians in World War I. The followup on the British cases has shown the results to be so unfavorable that the surgeons and limbfitting surgeons there have condemned the operation completely, the chief cause being imperfect stumps which result from surgery done in the presence of, or too soon after, sepsis. Many Canadian surgeons, however, strongly advocate the operation whenever it is indicated. The authors do the same, basing their opinion upon the results in 75 amputations done in the Army.

The normal tough plantar skin of the heel is brought forward directly beneath the tibia where the weight of the entire body is transferred into the socket of the prosthesis without any friction against scarred areas. The stump is longer and gives better leverage and is capable of full end hearing, with or without a prosthesis. The Syme prosthesis does not extend above the knee and is easier to fit than a below the knee stump. The Syme amputation also

Fig. 2. A, All soft tissue structures are divided in the line of the skin incision, down to the bone. The ankle is dislocated forward by cutting the talofibular and calcaneofibular ligaments from the inside of each malleolus. B, In short foot stumps the bone hook is then inserted into the talus to facilitate pulling the parts forward, while the calcaneus is dissected extraperiosteally out of the heel flap.

Fig. 3. A, After the calcaneus has been dissected out extraperiosteally, the malleoli are exposed and sawed off. 1. Peroneus brevis. 2. Peroneus longus. 3. Nerve (superficial peroneal nerve). 4. Extensor digitorum longus. 5. Anterior tibial. 6. Extensor hallucis longus. 7. Saphenous vein. 8. Posterior tibial tendon. 9. Flexor digitorum longus.

10. Medial plantar nerve. 11. Lateral plantar nerve. 12. Flexor hallucis longus. B, The saw line is placed as far distally as possible, and usually some of the articular cartilage on the end of the tibia is left (see Fig. 4A).

Fig. 4. A, All tendons and nerves, except the tendo calcaneus, are pulled down, cut at the saw line, and allowed to retract proximally. The white island in the center of the end of the tibia represents cartilage. The heel flap is debrided and all muscle, fascia, periosteum, and loose devitalized strands of tissue are removed. B, The thick edge of the heel flap is trimmed: the sharp edge of the wedge faces anteriorly, for ease of closure. The tourniquet is then removed, and the remaining open vessels are clamped and ligated. Complete hemostasis is desirable.

edema is present it is relieved by bed rest, elevation, wrapping, and, if necessary, by novocaine block of the sympathetic trunk. Cultures should be taken from all open wounds and operation postponed until the cultures are sterile.

The authors describe their technique minutely.

In general, the operation is performed in three major steps:

The first step consists of the skin incision, dislocation of the ankle, and extraperiosteal removal of the calcaneus.

The second step consists of sawing off the malleoli, cutting tendons and nerves, debriding the heel flap, and ligating the major vessels. The saw line is placed as far distally as possible. Care must be exercised in handling the posterior branches of the tibial nerve, since they are so closely associated with the corresponding vessels.

The third step consists of clamping, or ligating the small vessels until a dry field has been obtained, closing the stump, draining, and dressing.

No subcutaneous sutures are used, and the resulting suture line lies straight across the anterior aspect

of the stump. The resulting lateral projection of the skin forming dog ears is never trimmed as this might devitalize the flap. The dog ears disappear later as a result of proper use of the compression bandage. It is important never to apply the postoperative dressing with the knee in flexion. The reader is referred to the original article for more exact details.

The leg is elevated on pillows and kept elevated until the wound is healed. The first postoperative dressing is changed in 24 hours, and the drain may be removed at this time or left in place for as long as 7 days. The stitches are removed on the fourteenth day, and the foot of the bed is leveled and elevation of the extremity is discontinued, but the limb is not allowed to hang down until the end of the third week after operation. If the circulation to the heel flap is threatened during the postoperative period, novocaine blocks of the sympathetic trunk are carried out while the patient is in bed. Ordinarily a walking pylon is applied between the third and fourth weeks and the patient is permitted up with crutches for the first week, after which he usually walks with

INTERNATIONAL ABSTRACTS OF SURGERY

full weight bearing, without support. After about 4 weeks of use of the plaster pylon a plaster mold of the stump and leg is taken for the permanent prosthesis and a second pylon is applied until the prosthesis is fitted.

In all 75 cases the immediate results were completely satisfactory to the patient and to the surgeon. No extended followup study has been possible, since the first patients in the series were operated upon only about 3 years ago.

VERNON C. TURNER, M.D.

FRACTURES AND DISLOCATIONS

Laurence, G.: Traumatic Nerve Lesions In Children after Supracondylar Fracture of the Humerus (Lésions traumatiques des nerfs au cours des fractures supra-condyliennes de l'humerus chez l'enfant). *Rev. chir., Par.*, 1946, 65: 87, 105.

In a series of 177 cases of supracondylar fracture, 21 nerve lesions were observed. The median nerve was involved in 11 cases, the ulnar in 6, and the radial in 4.

In all cases in which the median nerve was involved the distal fragment was displaced posteriorly. Six of these cases required surgery, in 3 of these the nerve was intact macroscopically but stretched over the end of the fragment, in 2 cases the nerve was caught between the fragments, and in 1 case the nerve was bruised. Complete recovery occurred in all within from 2 to 6 months. The most constant symptom was the absence of flexion of the second and third phalanx of the index was also impossible, and in 5 cases the flexion of the index was paralyzed in addition, but pronation and supination were not impaired in any case. As the median nerve courses close to the brachial vessels, the nerve lesion is often complicated by compression of the artery.

In contradistinction to paralysis of the median nerve, the symptoms in involvement of the ulnar nerve appeared only a considerable time (from 18 days to 7 months) after the fracture. The author believes that this delayed appearance of the paralysis is not due to secondary compression by the callus but to the fact that in the ulnar nerve it takes a longer time till the primary injury produces clinical symptoms. The nerve may have been injured by the trauma itself or, more probably, by forced retraction or heavy traction on a Kirschner wire. The typical claw hand position of the fourth and fifth fingers develops only after many months, if at all. The paralysis was treated by electrotherapy. Four of the 6 patients recovered completely.

In 2 of the 4 cases of paralysis of the radius, surgery was required to liberate the nerve, which in 1 case was caught between the fragments, and in the other case was compressed by the callus. Three of the 4 patients recovered completely.

It is important to differentiate between these individual nerve lesions and the ischemic paralysis due

to bruising or obstruction of the brachial artery. In the latter condition, all 3 of the nerves are involved.

WERNER M. SOLMITZ, M.D.

DeLuigi, E. L.: Isolated Traumatic Luxation of the Fibula (Le lussazione traumatiche isolate del perone). *Gior. ital. chir.*, 1946, 2: 157.

The medical literature contains only 21 instances of luxation at the tibiofibular articulations. The case here reported is the twenty-second, which has been verified by roentgen examination. There has been 1 report of luxation at the lower tibiofibular joint and 1 of luxation at both the upper and lower articulations. All the rest have been upper joint luxations and 17 of these, including the one here reported, have been examples of anterior luxation of the fibular head. This accident has been most prevalent in young males of from 15 to 35 years of age, and has nearly always occurred in sports as the result of the long jump, that is, the result of indirectly applied forces.

The case here reported was that of a 24 year old student who was performing an exercise consisting of leaping into the air and turning about. Instead of landing upright and with both feet simultaneously, the student struck the earth with the right foot and thigh and with his body doubled up like a book. The right heel received an especially severe blow. There was a sensation of grating at the knee with severe pain, and the victim was unable to rise from the ground.

The head of the fibula was easily pushed back into place while the leg was maintained at 90 degrees flexion and the foot in internal rotation and dorsiflexion. The patient was discharged 25 days later, completely healed by means of ordinary physiotherapeutic measures.

JOHN W. BRENNAN, M.D.

ORTHOPEDICS IN GENERAL

Niebauer, J. J.: Development of Squamous Cell Carcinomas In the Sinus Tracts of Chronic Osteomyelitis. *J. Bone Surg.*, 1946, 28: 280.

Two cases of squamous cell carcinoma, arising from epithelized, chronic sinuses of bone, were seen in the Orthopedic Division of the Department of Surgery of the Stanford University School of Medicine.

The malignant degenerative change may occur as cauliflowerlike epitheliomas arising deep within the sinus, and diagnosis may be difficult unless biopsy is done in the operating room under direct vision of the entire sinus. Malignant change develops most often between the ages of 40 and 60 years in sinuses with osteomyelitis of from 20 to 50 years' duration. Increased foul discharge, increased pain, bleeding from a sinus, and pathological fracture are indicative of malignant change. The carcinomas tend to be well differentiated squamous cell epitheliomas with little tendency to metastasize.

Amputation is usually the best method of treatment.

VERNON C. TURNER, M.D.

Caldwell, G. A., Broderick, T. F., Jr., and Rose, R. M.: Sympathetic Block of the Stellate Ganglion. Its Applications In Orthopedic Conditions. *J. Bone Surg.*, 1946, 28: 513.

The diagnostic, prognostic, and therapeutic applications of sympathetic block to the lower extremity are well known and have been employed frequently. In contrast, regional block of the sympathetic nerves supplying the upper extremity has been neglected. Stellate block is equally applicable not only to similar conditions of the upper extremity, but to many other painful conditions as well.

The authors employed infiltration of the stellate ganglion with procaine hydrochloride in approximately 400 cases of painful orthopedic lesions in the upper extremities, from which they selected for presentation 18 cases of acute subdeltoid bursitis, 12 cases of periarthritis, 5 cases of myositis and fibrositis, 8 cases of hypertrophic arthritis, 5 cases of the infectious arthritis, 25 cases of pain and swelling following trauma, and 5 cases of causalgia following trauma. In each category, only those cases were chosen which had been followed up carefully.

The authors tried all the approaches described in the literature and obtained the most consistently satisfactory results from modifications of the descending infiltration technique of De Sousa Pereira.

In technique I, the patient is supine, with the head rotated to the opposite side to make the sternocleidomastoid muscle stand out. The sixth cervical vertebra is located in relation to the seventh cervical spinal process posteriorly, and to the cricoid cartilage anteriorly. The finger, inserted toward the sixth

cervical transverse process, displaces the sternocleidomastoid and the carotid sheath structures laterally, and the trachea medially. The finger is pushed in until it touches the sixth cervical transverse process or the region of origin of the scalenus anterior, and is held there. The needle is inserted directly below and parallel to the finger until it touches or approximates the transverse process.

In technique II the patient is supine. The head is turned up and away from the side to be blocked, in order to make the sternocleidomastoid muscle stand out. The sixth cervical transverse process is located as before. The sternocleidomastoid and external jugular vein are displaced anteriorly and the needle is inserted at right angles to the tip of the thumb, which is held on the posterior margin of sternocleidomastoid, anterior to the sixth cervical transverse process.

The authors conclude that in cases of recent acute lesions of the upper extremity, stellate block affords relief from pain which is almost universally gratifying. In chronic cases in which the lesions have been present until such anatomical changes as adhesions, erosion of cartilage, or aberrant calcification have supervened, only transitory relief from pain can be obtained and adjunctive physical therapy should be employed. The range of physical therapy tolerated is in direct proportion to the relief of pain afforded by stellate block; and in cases showing definite but transient improvement, it may be well to consider blocking with more noxious chemicals, such as alcohol derivatives, or even employing sympathectomy.

RUDOLPH S. REICHER, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Chetverikow, H. G.: Concerning Vasospastic Disease (Morbus vaso-spasticus). *Trachebnoe Delo*, 1946, No. 1-2, p. 22.

Intermittent attacks of pain, characterized by disturbances of the blood vascular system, have been classified into various symptomatic groups, which have been discussed as true diseases, each demanding its own method of treatment.

The author discusses the evidence for the common vasospastic origin of such divergent manifestations as hemicrania, angina pectoris, crises of abdominal and renal pains, hemorrhagic brain insult, essential meningeal hemorrhage, the vasomotor Ménière's syndrome, Raynaud's disease, true epilepsy and ulcer pains, and suggests that these manifestations be placed under one group and be designated morbus vasospasticus. These conditions have previously been tentatively grouped together and ascribed to a general disturbance of the cardiovascular tonus; however, the author thinks that the basis for them may be found as much in the pathological irritability of the sensory and motor apparatus distributed in the walls of the vessels, as in the conditions of tonus of the constituent smooth muscle fibers. He agrees with other writers in that he thinks that this irritable condition acts under the influence both of the central nervous system, and of chemical irritants arriving by way of the blood stream.

The author has had the opportunity of studying a number of patients in whom 2 or more of the cited painful syndromes had developed concurrently, or in succession, and he gives 3 case reports in an attempt to emphasize the general evidence of interdependence among these different symptomatic conditions.

All of the patients were in middle life and all had a long history of cyclic, or rhythmic, attacks of migrainelike pain in the head with temporary darkening, or even momentary loss of consciousness (disturbance of the cerebral circulation). In all, these head pains were followed or preceded, at greater or lesser intervals of time, by rather typical attacks of angina pectoris, with the pains radiating to the left shoulder and hand, and all of the patients sooner or later developed painful crises in the abdomen, which in 2 instances could be controlled by heat treatments and vasodilative drugs and other more simple measures. In the third case, however, an old syphilitic with evidence of generalized arterial involvement, the abdominal crises eventuated ultimately in an acute abdomen and death. The autopsy in this instance disclosed a mural thrombus of the abdominal aorta, a fresh thrombus in the superior mesenteric artery with spotty necrosis of the small intestines, and, of course, acute peritonitis. In this corpse there were also disclosed areas of cerebral softening, and of myocardial and hepatic degeneration.

The author believes that these cases can be explained as far as the principal manifestations are concerned by the assumption of a common spastovascular disease involving various segments of the vascular system with consequent variance of the clinical manifestations.

JOHN W. BRENNAN, M.D.

Halle, J.: Preservation of the Vein in Operations for Arteriovenous Fistula. *Lancet*, Lond., 1946, 2, 85.

Although the usual operation for arteriovenous fistula has been proximal and distal ligation of both the involved artery and vein, the author finds that such a procedure is frequently followed by symptoms of venous obstruction. Patients complain of pain with dependency or heating, dependent edema, cyanosis, and engorged veins. These manifestations are exaggerated by sympathectomy.

In patients with acute arterial injury requiring ligation of a main artery, simultaneous venous ligation probably decreases the danger of gangrene. However, because of the rich collateral circulation which develops in the presence of an arteriovenous fistula, sacrifice of a main artery is well tolerated.

In a small number of cases all arterial connections of the arteriovenous fistula were severed but the vein was left intact. The authors believe that preservation of the vein resulted in less residual disability.

TUFOORE B. MASSELL, M.D.

Leriche, R.: Thrombotic Obliteration of the Bifurcation of the Aorta (De l'oblitération thrombotique du carrefour aortique). *Lyon chir.*, 1946, 41: 3.

A syndrome is described which results from obliteration of the bifurcation of the aorta by thrombosis. The author believes that the thrombus usually begins in one common iliac artery and progresses gradually toward the aorta until, finally, both iliac arteries and the bifurcation are obliterated. In some cases the process may originate in the aorta whence it spreads down the iliac arteries. While recanalization may occur it is of no functional significance. Generally there is an intense periarteritis around the thrombosed aorta involving the lymph nodes and the distal end of the sympathetic chain. Probably the thrombosis originates at the site of an atheromatous plaque. The condition occurs most often between the ages of 45 and 60 but the author has noted the first manifestations before the age of 30.

The symptoms are of gradual onset and manifest themselves in the genitalia as well as in the lower extremities. Subjectively, the patients complain of extreme fatigability of the lower extremities rather than true intermittent claudication and they find it impossible to maintain an erection because of the diminished blood supply to the cavernous bodies. On examination the calves and feet are pale even in the upright position; there are no palpable pulses be-

low the aorta and there is a generalized atrophy of both lower extremities. Oscillometry confirms the absence of arterial pulses, although a slight vibration is often perceptible in the upper thigh. The blood pressure is slightly elevated in the upper extremities. If the patient has had any wounds anywhere in the legs or thighs they frequently will have failed to heal and instead will have formed indolent ulcers. The diagnosis can be confirmed by x-ray visualization of the aorta under pentothal anesthesia, but the author points out that this procedure is not without danger.

The disease progresses very slowly but results in gangrene after from 5 to 10 years. The gangrene is of gradual onset, is likely to be of the dry variety, and may appear simultaneously in several areas from the trochanters to the toes. It progresses slowly, is associated with intractable pain, and ends in cardiorenal failure or terminal pneumonia.

The slow progress of the disease is explained by the rich collateral circulation to the femoral vessels from the lower aorta. The termination is thought to be the result of upward extension of the thrombosis and, at times, involvement of the accompanying veins.

Treatment consists of bilateral lumbar sympathectomy and resection of the bifurcation of the aorta. In resection of the lumbar ganglia a high sympathectomy (including L1) is advocated, not only because the vasomotor supply to the collaterals through the pelvis originates at a fairly high level, but also because it is believed that a high incision is less likely to destroy any of the needed collateral vessels. Resection of the terminal aorta and the common iliac arteries may be extremely difficult because of the marked degree of periarterial scarring which accompanies this condition. While the author suggests the desirability of performing the entire operation in one stage, he notes that most often a 2 stage procedure is necessary. At times he has had to limit himself to sympathectomy alone without resection of the thrombosed arteries. However, he considers the latter procedure inadequate because it fails to halt the upward extension of the thrombosis in the aorta. When resection is carried out it should extend up to a level at which the aorta is patent. Several case reports are given in some detail. THEODORE B. MASSELL, M.D.

Frieh, P., and Morel, A.: A Case of Obliteration of the Bifurcation of the Aorta (Leriche's Syndrome) Treated by Resection of the Bifurcation (Un cas d'obliteration du carrefour aortique [syndrome de Leriche] traité par la résection du carrefour). *Lyon chir.*, 1946, 41: 17.

A case report is made of a male, 43 years old, who first manifested intermittent claudication in both legs, sensitivity to cold, diminished amplitude of pulsations (ascertained by oscillometry) and absent palpable pulses below the femoral canal. While under observation all pulsations disappeared in both lower extremities and the patient lost his sexual power completely.

At operation the terminal aorta and both common iliac arteries were found to be obliterated by an

organized thrombus. Considerable perivascular scarring was encountered around the thrombosed vessels. The bifurcation of the aorta was excised along with the second and third left lumbar sympathetic ganglia. Return of sexual function occurred within 15 days. Two months later the third right lumbar ganglion was excised.

Eighteen months later both feet were still warm, intermittent claudication was still present, but exercise tolerance was improved. The sexual function remained satisfactory.

THEODORE B. MASSELL, M.D.

Higgins, W. H.: Periarthritis Nodosa: Clinical Manifestations and Postmortem Findings, with a Report of 6 Cases. *South. M. J.*, 1946, 39: 453.

The clinical manifestations and laboratory findings of periarthritis nodosa are protean, depending on the organs involved and the stage of advancement. More commonly the symptoms at the onset are gradual and present the picture of sepsis of unknown origin. As the disease progresses, one's attention is drawn to certain organs or systems which contribute to the confusion, and to frequent errors in diagnosis. Fever, malaise, abdominal discomfort, dyspnea, and paresthesias are common complaints.

Specialists in different branches of medicine have reported the disease as simulating well known clinical entities ranging from obscure neurological syndromes to trichinosis or undulant fever. Laboratory studies are not particularly helpful except in a negative way, unless an eosinophilia is present. In 1939, Rachemann reported the frequent occurrence of eosinophilia, sometimes reaching a concentration of 60 to 80 per cent of the white cells. This is particularly true when asthma is a part of the symptomatology. In fact it is his conclusion that the particular symptom complex characterized by asthma of the intractable type, pain and numbness in the extremities, and an eosinophilia in the blood of at least 25 per cent, is probably periarthritis nodosa, and the prognosis is bad. A moderate to high leukocytosis is generally present.

The article deals with 6 proved cases of periarthritis nodosa, one of which is from the personal files of the author. The others are taken from the records of the Medical College of Virginia. An analysis of these 6 cases shows a remarkable similarity of complaints notwithstanding the fact that the histories were taken by different individuals of varying abilities. In practically every instance in these and other reported cases the symptomatology is so strikingly similar that one is surprised at the small percentage of correct ante mortem diagnoses. It is probably true that at least 95 per cent are recognized only by the pathologist, and many other cases are incorrectly diagnosed clinically as such, with final recovery. Unfortunately a biopsy only occasionally provides the necessary information, since the nodules are seldom accessible and a section of muscle rarely contains the specific vascular changes. In spite of a general glandular enlargement these structures only

infrequently are diagnostic, and their removal is not as a rule helpful.

The most promising material for study is the vascular nodules and skin lesions such as purpuric spots which are occasionally found. In fairness to the clinical staff it should be remembered that the usual symptoms are in no way specific and may apply equally to a large number of other clinical entities.

In the present series, the ages of the patients varied from 31 to 55, although reports on children as young as 2½ years are on record. Males are affected four times as frequently as females, and about 50 per cent of cases are found in the third and fourth decade of life. Approximately 300 cases are now in the literature and, naturally, many more are unpublished.

A composite picture of a typical case of periarthritis nodosa could be woven into the record of a young man who for several months had been suffering from loss of weight, weakness, generalized pain in the joints and abdomen, swelling of the ankles, dyspnea, and marked anemia. He would probably have some neurological manifestations such as optic atrophy, numbness of his extremities, and weakness of one or more groups of muscles. He would show evidences of cardiovascular renal disease, and his temperature would vary over a long period. His blood would show a marked anemia, leukocytosis, and possibly an eosinophilia. If, as Rachemann has pointed out, sensory disturbances are included with this syndrome, the diagnosis of periarthritis nodosa is probable. Considerable interest is being shown in the neurological manifestations. Boyd has reviewed various psychiatric disturbances presenting such syndromes as delusions of persecution, negativism, and dementia. These syndromes have been noted chiefly in the older group. Other symptom complexes have shown meningeal irritations characterized by convulsions, either generalized or Jacksonian.

Three of the author's patients had spinal fluid pressures of over 200 mm. of water, 1 patient gave a history of recurring convulsions, and 2 others developed mild delirium. Not infrequently the mesenteric vessels and adrenal glands show typical vascular changes. Death occurs in at least 90 per cent of cases, most commonly as a result of hemorrhage from a viscus, from perforation in the intestine secondary to an infarct in the mesentery, or from renal failure. In this series there were 2 fatal intestinal perforations and 1 hemorrhage from a liver aneurysm.

Periarthritis nodosa, therefore, presents a multiplicity of pathological and clinical manifestations, and the condition should be considered as a possibility in every patient with obscure or generalized symptoms.

BENJAMIN GOLDMAN, M.D.

Lindskog, G. E.: *The Surgery of the Innominate Artery*. N. England J. M., 1946, 235: 71.

The author has reviewed the literature on the subject of surgery of the innominate artery. The indications for, and the technique and results of opera-

tion are discussed. Eighteen cases have been added since a review by Greenough in 1929, and a total of 107 cases of ligation, excision, or suture of the innominate artery, with an operative mortality of 54 per cent, are recorded. Since 1900 there have been 61 cases, with a mortality of 31 per cent. Nineteen cases of survival after surgery for innominate aneurysm; including the case presented by the author, are tabulated. A report of this case is presented in detail.

Ligation of the innominate artery has been performed for 4 indications: (1) recent wounds of this vessel and its two major branches, 11 cases, (2) traumatic aneurysm of the innominate, subclavian, and carotid arteries, 20 cases, (3) spontaneous (usually syphilitic) aneurysm of these vessels, 75 cases, and (4) control of remote bleeding, 1 case. A table showing the indications and the results is presented.

There can be no question of the propriety of, and necessity for operation in traumatic lesions of the innominate artery and its bifurcation. The situation is urgent, and many of the patients have not survived the immediate injury, which is usually due to a gunshot, shrapnel, or stab wound.

The problem of syphilitic or nonspecific aneurysm (usually called "spontaneous aneurysm") requires more detailed consideration and evaluation of data. Practically all these patients have had diffuse arterial and complicating visceral disease. The average age in this group was 47 years. The average age in the traumatic cases was 28 years. The incidence of therapeutic failure, especially after simple ligation, was higher in the spontaneous aneurysms than in the traumatic cases. The life of a patient afflicted with such an aneurysm is usually a miserable one because of pressure symptoms, which include severe pain, dysphagia, hoarseness, and dyspnea, and there is always the ominous threat of rupture into the pleural cavity or trachea or through the skin as a terminal event.

A few reported cases with small aneurysms in the third subclavian area, because of their small size and position, the presence of brachial pain, and the absence of clinical syphilis, were reminiscent of aneurysm due to cervical rib. However, they hardly constituted a proper indication for the operation as performed, since this type of case does not have a tendency to progression and is satisfactorily managed by local surgery.

The ideal treatment of an aneurysm, whether traumatic or spontaneous, is either a Matas end-aneurysmorrhaphy or proximodistal ligation and excision of the sac. In the case of the innominate artery the Matas operation does not lend itself to practical application, and there is no record of its deliberate use. Complete isolation and excision of the sac have been accomplished in only 3 cases, in all of which the results were successful. Resort to the simpler procedure of ligation in continuity has been the rule, because of technical difficulties or the patient's condition. Proximal ligation of the innominate artery with ligation of the carotid and subcla-

vian arteries distal to the aneurysm (the so-called triple operation) has been performed more frequently than has radical excision, and the results have been better than those of proximal ligation alone.

The author notes that in 9 of 58 cases, cerebral complications are reported to have caused post-operative death, and temporary disability occurred in a few other cases. The average age in the fatal cerebral cases was 40.0 years, as compared with 42.5 years for the entire series. These facts suggest that the inherent vascular pattern is of more importance than the age factor.

Not a single case has been reported in which gangrene of the upper extremity followed ligation of the innominate artery, a fact that emphasizes the abundant collateral vascular pathways in the shoulder girdle and axilla (intercostal-subscapular). The occurrence of late ischemic pain, paresthesia, and muscular weakness in the arm, however, has occasionally been noted and quite generally disregarded from the therapeutic standpoint. Although aneurysm of the innominate artery frequently produces Horner's syndrome on the right side, there is recorded evidence in some cases that a sympathetic release with vasodilatation occurs in the vessels of the right upper extremity within 12 to 24 hours after operation.

In view of the technical difficulties connected with exposure of the innominate artery and the high mortality in the earlier cases, various indirect or simpler therapeutic approaches for aneurysm of this

artery have been devised and tried. One is the application of the wiring technique, which has been associated with uncertain results and with the complications pertaining to this method in other vessels. A second is the technique of Brasdor-Guinar, namely, ligation of the subclavian and carotid arteries distal to the aneurysmal sac. The author notes that long term cures of from 5 to 21 years have been reported with the use of this method.

Finally, innominate aneurysm has been treated by the creation of an arteriovenous fistula between the common carotid artery and the jugular vein with an end-to-end technique. Eight such cases have been reported by McCarthy. All of these cases had positive serological reactions at the time of operation. There were 2 operative deaths, one apparently due to anesthesia and the other to embolism, and 2 later deaths, one at 5 weeks from myocardial failure and the other at 4 weeks from rupture of the aneurysm. Four patients survived, 1 for more than 4 years, and 2 of them were able to resume work.

The earliest operations on the innominate artery were carried out through a cervical or supraclavicular muscle cutting incision. It seems clear that adequate and safe exposure for surgery of the innominate artery demands some type of clavicular and manubrial section or resection. A median section of the manubrium carried through to the second interspace, with section of the right clavicle in its medial third, gave adequate exposure and a good result in the author's case.

HERBERT F. THURSTON, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE; POSTOPERATIVE TREATMENT

Bauer, G.: Thrombosis, Early Diagnosis, and Abortive Treatment with Heparin. *Lancet*, Lond., 1946, 1: 447.

The available figures suggest that thromboembolic complications occur after about 1.6 per cent of all surgical operations, or in every sixtieth patient. Of these patients every sixth one dies of pulmonary embolism. Of the women in childbirth, (about 1.2 per cent) every eightieth one develops this complication, and of these not quite every twenty-fifth one dies. Among the patients in medical wards the incidence and mortality from this condition are just as among those in the surgical wards generally. In cases of fracture or other trauma of the lower limbs thrombotic complications are particularly common, with an incidence up to 15 per cent.

The incidence and mortality seem to have remained unaltered for several decades. Now, however, a change for the better appears possible through the use of specific anticoagulative remedies.

Heparin can be used as a prophylactic, but is best employed as a remedy for already existing thrombosis. To obtain the best results the diagnosis must be made at the earliest possible stage. It now appears to be established that the process almost always begins in the deep veins of the lower leg. Diagnosis at this early stage is facilitated and confirmed by phlebography.

If intensive heparinization is instituted at this stage, with doses from 300 to 500 mgm. (from 24,000 to 70,000 international heparin units) a day according to a definite schedule, the disease is generally aborted. After from 3 to 5 days the acute symptoms usually subside, and the pulse and temperature return to normal. As a rule it is then possible to allow the patients to get up. They can leave the hospital within a few days and soon resume their work.

More advanced thrombosis accompanied by phlegmasia alba dolens responds well to the same treatment, but requires more time and larger doses for cure.

Massive pulmonary embolism reacts favorably to heparin. Large doses, administered early, prevent further deposits on the embolus, and generally carry the patient over the first critical 24 hours, after which recovery is almost as quick as in uncomplicated thrombosis.

In a series comprising 622 patients with thrombosis treated on this principle in Sweden, there were only 5 deaths. Good results have also been reported from Canada. Thus it now seems possible, with the aid of heparin, to reduce the mortality from thrombosis to under 1 per cent, as compared with the previous figures of from 16 to 20 per cent for surgical and medical cases and from 3 to 5 per cent for obstetrical cases.

In the past the period by which the stay in the hospital has been prolonged by an attack of thrombosis has been about 6 weeks. With heparin treatment it is generally no more than from 6 to 9 days.

Clinical and phlebographic studies have shown that patients surviving thrombosis develop serious after effects which have received too little attention. They all suffer permanently from swelling of the affected leg, while 9 of 10 eventually show indurative lesions on the lower leg, and 4 of 5, leg ulcers. From 80 to 90 per cent of ordinary leg ulcers seem to be caused by a deep thrombosis suffered at an earlier period. All these disorders and their social consequences can be avoided if thrombosis is treated with heparin at an early stage.

The risks associated with heparin therapy are slight. When the drug is used for the treatment of manifest thrombosis there is hardly any danger of its inducing hemorrhage. Experience up to date does not point to any contraindications.

JOSEPH GASTER, M.D.

Jorpes, J. E.: Anticoagulant Therapy in Thrombosis. *Edinburgh M. J.*, 1946, 53: 222.

The author believes that we now have effective agents, heparin and dicumarol, for the prevention of intravascular coagulation during life, and by means of them thrombosis and pulmonary embolism can be combated. He called attention to only 2 details regarding heparin, namely, its physicochemical properties and its formation by the mast cells of Ehrlich.

The author presents in tables various aspects of his study, such as the frequency of pulmonary embolism and of deaths from pulmonary embolism in cases of thrombosis from the large statistical series in the literature; the comparison between conservative (1929-1938) and heparin (1940-1945) treatment of thrombosis; the frequency of thrombosis and embolism after surgical operations, childbirth, gynecological operations, and in medical cases in 19 Swedish Clinics from 1940-1945; the stay in bed and rise in temperature of 790 patients with deep venous thrombosis who were given no special treatment nor treated with heparin, heparin and dicumarol, or with dicumarol alone; the spread of pulmonary embolism to the second leg; the progressive and post-thrombotic sequelae in 790 cases of deep venous thrombosis given no special treatment or treatment with heparin, heparin and dicumarol, or with dicumarol alone; the post-thrombotic sequelae after 2 to 5 years in 103 cases of deep venous thrombosis following regular heparin treatment at the Mariestad Hospital from 1940 to 1945.

These facts concerning the use of heparin in Sweden and Canada, as supplemented by the findings in conjunction with dicumarol, justify the statement that the most usual forms of thrombosis can now be effectively combated. With early diagnosis and reg-

ular treatment with an anticoagulant, there is practically no mortality from diagnosed and uncomplicated thrombosis of the leg or from pulmonary embolism which is not instantaneously fatal. Failure to prevent death or spread of the process to the thigh or other leg may in most cases, if not in all, be attributed either to neglected diagnosis or defective treatment. It is evident that the medical gymnastics and early getting up of the patient can reduce the incidence of thromboembolism. This fact has been admitted by several authors, but these factors are less reliable as therapeutic agents in cases of acute venous thrombosis or pulmonary embolism. Instead of novocain block of the lumbar ganglia suggested by Leriche and Ochsner, venous ligation with or without thrombectomy has been preferred by the many recent users. Even in the selected cases, however, anticoagulant therapy could be of value to check further thrombosis in the operative field.

Regarding the mortality rate, a great saving of human lives could be obtained if recent treatment with heparin or, if possible, with dicoumarol, is given; also, the mortality of thromboembolism could further be greatly reduced through more careful observation of the earlier signs of thrombosis. Fatal casualties are rare in clinics where due attention is paid to early diagnosis. When anticoagulant therapy is used the time in the hospital is shortened by about 1 month. An early heparin treatment prevents a considerable number of thrombotic patients from developing subsequent disabling ulcers or induration in one or both legs. **EMIL C. ROARNSNEK, M.D.**

Clarkson, P., and Lawrie, R. S.: The Management and Surgical Resurfacing of Serious Burns. *Brit. J. Surg.*, 1946, 33: 311.

This article is based on the management of 800 serious burns, sustained in the Mediterranean theatre of combat, and the problem of skin grafting in 192 of these cases during the intermediate (healing) and late (rehabilitation) phases. Grafting was performed in all instances when the full thickness of the skin was destroyed. The intermediate phase started in the second week and comprised the preparation of the patient and of the burned area for grafting, and the application of grafts and their care until healing was complete. Surgery in the late phase was necessary only for that minority of cases in which there was functional disability from the primary cover. The ideal treatment was to cover the raw area as early as possible with new skin which met the full functional and cosmetic need of the part, but a granulating surface did not always accept a thick free graft, and a thin graft, which always contracts later, might have caused disability. Because of this, some areas were treated in 2 stages; a primary cover was provided by thin free grafts and these were later excised and replaced by thicker grafts or flaps.

Petroleum products, phosphorus, and cordite, in the order given, were the most common causes of military burns, the first causing all 13 cases which presented a total skin destruction of more than 50 per

cent of the body surface. Seventy-two per cent of the cases were found to have a full thickness loss of skin involving more than 10 per cent of the body surface; 20 per cent presented complete burns of more than one-third of the body. Almost every patient with 1,000 sq. cm. or more of raw granulating surface was constitutionally ill until the raw area was substantially reduced below this figure. Thus, the management of a seriously burned patient has 2 main aspects: (1) the metabolic problem, and (2), skin grafting as early as possible.

The initial standard local treatment (admittedly far from ideal) was gentle débridement under pentothal, followed by a dressing of sterile vaseline gauze. Serious burns travel poorly after the first 6 to 12 hours and this necessitated holding the delayed cases forward. The main purpose of early treatment is to restore the circulation, and this was done, chiefly with copious quantities of plasma. Progress was checked by means of hemoglobin, blood pressure, and pulse determinations made every 3 hours. After anemia commenced, within a week or two, transfusions were administered in amounts sufficient to maintain an average hemoglobin of between 80 and 100 per cent. Often this was difficult until the granulating surfaces were healing with grafts. Planned, palatable diets with iron and vitamin C were given.

The important thing in healing was not the size of the burned area, but the resurfacing program and the time table to which it was geared. Of fundamental importance in healing raw areas was early grafting. Early grafts took best, grew more rapidly, and the raw areas were healed sooner. It usually took from 12 to 18 days after the burn to assess the areas of full thickness destruction accurately and to excise the sloughs under anesthesia. Two days later, closely packed thin patch grafts were applied, and shortly after this the patient was healed. This was the rapid time table aimed at. Of course, in extensive burns surgical removal of the sloughs was impossible because of the blood loss and shock which followed. These patients were handled at a slower, nonoperative pace that required patience, skill, and a large ward staff.

In assessing the burn depth, it was found helpful to obtain a history as to the provocative agent, the circumstances, the duration, and the clothing. Accurate assessment, however, always required recognition of the appearance of burns of different depths. The authors arbitrarily recognize 3 chief depths of burns—epidermal, dermal, and full thickness loss—and discuss each thoroughly. Frequently, differentiation between the latter two depths was very difficult. In dermal burns, although destruction extends into the dermis, sufficient epithelial elements survive to permit spontaneous skin healing. This type of healing was unsatisfactory occasionally because of disabling contractures or persistent ulcerations and ultimately required resurfacing. Late definitive repairs formed only 10 per cent of the operations and consisted of thick dermatome sheets, postauricular Wolfe grafts, and rotation or forehead flaps.

For very large areas to be covered as quickly as possible, the authors found that multiple thin patch grafts had a 90 to 100 per cent take, even on indifferent surfaces. They reason from this that primary cover by the suspension of minced skin may become practicable. Although a "primary final" repair could be obtained by a successful sheet graft for limited areas, such a graft was followed by contractures, was harder to use and apply, and did not "take" as often as did the patch graft. Therefore, this type was seldom used except for special sites, such as flexor creases and the hands. A 50 per cent gum acacia glue was preferred to Sano extracts for fixation. Pinch grafts were condemned. If the patch grafts were closely padded and thin, the ultimate scar was not unsightly.

The authors used both, but preferred the Blair knife to the Padgett dermatome. Cyclopropane was the anesthesia of choice and pentothal was used occasionally, but only for induction because of the frequency of liver damage. In extensive burns grafting over 1,000 sq. cm. was performed at each operation, from 3 to 7 day intervals intervening between stages. Since the routine use of penicillin, streptococcal infections ceased to be a major concern after the grafts were applied. The cause of perichondritis which occurred in 5 per cent of the cases as a late complication remains unsolved and treatment is unsatisfactory. In addition to infectious and cicatricial complications, pyoderma and sunsensitivity of the healed burned skin were not uncommon.

There were 3 late deaths in the group of 192 cases, none of which was due to burns. The authors conclude that death is not inevitable in cases of burns of up to 70 per cent of the body surface, with areas of full thickness skin loss up to 5,000 sq. cm., which have thorough general treatment and prompt surgical resurfacing.

DAVID H. LYNN, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Smith, J., and Rank, B. K.: A Case of Severe Electric Burns with an Unusual Sequence of Complications. *Brit. J. Surg.*, 1946, 33: 365.

The authors report the case of an 18 year old man in the Royal Australian Air Force who suffered extensive severe electrical burns to the left arm and both legs, and 8 days later developed an acute gangrenous cholecystitis. Amputation of the upper extremity, of both legs, and a partial cholecystectomy were performed at successive intervals on this extremely sick patient. The postoperative course was complicated by bilateral pneumonia, an aborted empyema, and abscess formation in 1 leg stump and in 1 injection site. Satisfactory recovery occurred after 3 months.

The authors thought there was a possibility that the gall bladder complication was related to the extensive burn in some manner similar to Curling's ulcer of the duodenum. Because of the discrete appearance of gangrenous patches on this gall bladder

and the common blood supply of that viscus and the duodenum, an embolic process is suggested as the cause of these rare complications of severe burns.

WAYNE CAMERON, M.D.

Carney, H. M.: Wound Healing with Low Vitamin C Level. *Ann. Surg.*, 1946, 123: 1111.

This study concerns 100 soldiers who had been at the front in Italy on a ration of concentrated foods for at least a month. All but 2 per cent of the troops had discarded their only source of vitamin C, ascorbic acid contained in lemon powder. Their fasting plasma ascorbic acid levels, as determined by the technique of Farmer and Abt, were, in general, below the normal minimal range of from .7 to 1.0 mgm. per cent. The hospital diet was unable to raise their levels appreciably. No therapeutic doses of vitamin C were given.

Of the 100 men studied none showed clinical evidence of definite vitamin C deficiency. Sixty-eight had wounds of which 8 failed to heal (11.7%) and of this number, several showed normal plasma ascorbic acid levels. Many of these failures in healing were associated with infection and the author believed that most of them were due at first to inexperience in the closure of war wounds. Among the numerous factors responsible for the low incidence of failure reported by Crutcher (2 separations in 200 consecutive cases closed from 3 to 10 days following débridement), the following are emphasized: early and adequate débridement, use of incisions at the time of débridement that readily lend themselves to closure, proper splinting of the wounded part, early (4 to 5 day) closure of the wound in the operating room at the time of the first dressing by suture or skin graft, use of fine nonabsorbable suture material closing the skin only and without tension, the maintenance of normal blood constituents especially as regards the plasma protein, hematocrit, and hemoglobin levels, and the intelligent use of penicillin and the sulfonamides. Improvement in wound healing has come from these measures and not from fortifying the diet with vitamin C.

The author concludes that no relationship between plasma ascorbic acid levels and wound healing was observed.

DAVID H. LYNN, M.D.

Odum, G. B.: Causes of Amputations in Battle Casualties with Emphasis on Vascular Injuries. *Surgery*, 1946, 19: 562.

This report is a result of a detailed study of 1,833 amputations carried out in the Third United States Army. In no case was amputation done without consultation. All surgeons were made cognizant of the latest work on vascular repair. Conservatism was always emphasized. The main causes of loss of limb in order of frequency in World War II were: traumatic amputation, vascular injury, and gas gangrene. It is noteworthy that the fourth cause of amputation in World War I, secondary infection, has been eliminated by early adequate débridement and the use of penicillin and sulfonamides. The direct

results of mine injuries are shown—1,375 cases of lower extremity amputations as compared with 458 of the upper extremity.

Clostridial infection was encountered in 445 patients, of whom 258 came to amputation. Clostridial infections were classified as follows: (1) diffuse clostridial myositis in which an amputation as far above the visible evidence of involvement as possible was performed immediately; (2) clostridial cellulitis involving only a muscle or group of muscles, in which wide incision of the localized process and excision of the devitalized tissue were sufficient; and (3) localized clostridial abscess in which incision and drainage were all that was necessary. Diffuse clostridial myositis accounted for 14 per cent of the total number of amputations.

By far the greater number of patients seen in the military hospitals of this country, who were minus an extremity, lost that member immediately when hit, or it was so badly mangled that the damage was beyond repair. This group of cases accounted for 63 per cent of all the extremities amputated.

In the group of vascular injuries the greatest salvage of extremities can be accomplished. This group borders on the traumatic group closely, but when the surgeon believed that the injury to the blood supply was the paramount lesion the injury was classified as vascular. Blood vessel injuries were the cause of amputation in 23 per cent of the cases. There were sufficient vitallium tubes and heparin available to give this nonsuture method a fair trial. Some of the procedures advocated by Blakemore and his associates are impractical for use in the field for the following reasons: (1) the recognition of injury to a major vessel by an aid man on the battlefield is impossible, and the therapy cannot be instituted by him; (2) the institution of surgical procedure in the battalion aid station, where only resuscitation has been practiced, would require the revision of the entire system of handling casualties in forward areas (since vascular injuries constitute less than 1 per cent of the total number of casualties, such a change would not be justified); (3) although the time interval between wounding and the institution of surgery has been greatly reduced in World War II, it still ranges between 6 and 12 hours, even in emergencies; (4) the preparation of fresh vein grafts was time consuming (if frozen grafts had been available this objection would have been removed); and (5) the use of heparin in battle casualties entails considerable risk, because of the frequency of multiple wounds and the danger of fatal hemorrhage.

Only the larger arteries, including the subclavian, axillary, brachial, iliac, femoral, and popliteal, were repaired. Comparing the results of repair with ligation on the same group of vessels, it was found that when the major vessel was ligated 57 per cent of the involved extremities developed gangrene, but when repair was the method of choice only 38 per cent developed gangrene. Although the repair series was much smaller, and the more favorable cases were selected for repair, it was believed that there was a

distinct advantage when repair was used. In comparing the suture (42 cases) and nonsuture (28 cases) methods of repair, it was found that the incidence of gangrene following repair was approximately 50 per cent for both groups. The Blakemore method of vein graft appeared to have a slight advantage over the other nonsuture methods used. Repair by suture remains the method of choice whenever applicable even if it means the reduction of the caliber of the vessel by as much as 50 per cent.

A comparison between the incidence of gangrene following ligation in battle casualties and comparable injuries in civilian practice shows a much higher incidence of gangrene in the former. This is true in spite of simultaneous division of the companion vein and the routine use of sympathetic blocks before and after surgery. It is believed that the major part of this difference is due to the fact that the battle casualty has had the injury for from 6 to 12 hours before he reaches a surgical unit. He is often exsanguinated, has low blood pressure, and is in shock; his tissues are anoxic. There is often hemorrhage into the fascial planes of the extremity with a resulting hematoma and pressure on the collateral circulation. Often the collateral circulation has been injured also. The disappointing results from sympathetic blocks are accounted for by these facts rather than the fact that the blocks were not well done.

JOHN L. LINQVIST, M.D.

Conway, H.: Anaerobic Infection and Gangrene of War Wounds in Casualties from the Philippine Islands. *Surgery*, 1946, 19: 553.

An analysis of 37 cases of anaerobic infection or gangrene complicating war injuries is presented. These cases represented 0.9 per cent of 4,040 surgical battle casualties. Following early treatment at forward stations the patients were admitted to the hospital from 5 to 21 days after injury. Thus, the analysis is concerned with the management of late complications.

The mere finding of pathogenic clostridia in a wound is not of importance. The *Clostridium welchii* was recovered from 13 per cent of the cultures made of all wound discharges from the 4,040 patients. The types and locations of wounds from which the *Clostridium welchii* was recovered show that these organisms contaminate certain wounds preponderantly. Seventy-five per cent of the wounds from which the *Clostridium welchii* was recovered were those in association with compound fractures. While fractures of the tibia and fibula made up only 13 per cent of all fractures, they accounted for 33 per cent of the compound fractures which were contaminated with the *Clostridium welchii*. Wounds of the buttock comprised only 5 per cent of all soft tissue wounds but accounted for 56 per cent of soft tissue wounds contaminated with the *Clostridium welchii*.

There were 14 patients with clostridial myositis, in 8 of whom the gangrene was limited to particular muscles, while in the remainder all the muscles of the extremity were involved in the spreading, necrotic

process. The lapse of time between injury and onset of the infection in this group averaged 10 days. Only 2 of the patients had not received penicillin continuously from the time of débridement until admission to the hospital, and only 2 patients had not had débridement under 6 hours. The chain of symptoms and findings in these patients were as follows: acute onset, very severe toxemia, severe pain at the site of injury and in the extremity distal to the point of injury, restlessness, thirst, tachycardia, fever, marked swelling of the extremity, cadaveric pallor of the skin of the extremity, and serous exudate, with or without gas bubbles from the wound. There may be a bronzed tint to the skin of the face, upper chest, and arms. Crepitation of the tissues was present in 6 patients and absent in 8. Roentgenograms showed gas in the tissues in 4 of the 8 patients who were examined by means of the x-rays. Peripheral pulses in the involved extremity were absent in 6 patients.

Operative therapy in 8 cases of localized clostridial myositis consisted of wide incision and drainage combined with excision of all the gangrenous muscle. In 2 of the 8 patients amputation was necessary. Intensive penicillin therapy was given after operation in all of the cases. It had no apparent effect on the toxemia or upon the course of the fever. Gas gangrene antitoxin was given to 6 patients after operation and discontinued on the fourth day because of severe urticaria. One patient died in toxemia following a long illness complicated by hemorrhage from the wound and gangrenous cholecystitis. Seven recovered following radical excision of muscle groups.

In 6 patients there was clostridial myositis in all the muscles of an extremity. All had been treated with penicillin from the time of injury until the onset of the disease. These were patients in whom there was an abrupt onset of signs and symptoms. The leucocyte count was extremely high. Four patients recovered following amputation, while 2 patients developed severe toxemia and died. The mortality rate in these 14 cases of clostridial myositis was 21.4 per cent.

There were 23 cases of anaerobic cellulitis. These did not include cases of localized abscess from which pathogenic clostridia were recovered. Anaerobic cellulitis was characterized by the gradual onset of diffuse edema of the subcutaneous and areolar tissues. Muscles were not involved. The average lapse of time between injury and onset of the complication was 15 days. All of these patients were pale, toxic, and febrile. They did not complain of pain, and their temperatures were not high. Penicillin had been given to 18 patients. On admission their casts were stained with blood and pus and had a foul smell. The usual procedure was to remove the cast and to institute balanced traction. It was following the use of this necessary measure that these patients developed anaerobic cellulitis. The impression obtains that the motion of fascial planes coincident to removal of the plaster cast and the institution of traction causes the extension of latent anaerobic infection. Commonly there was grayish slough in the

depths of the wounds. Thick, dark brown or yellow pus with bubbles of gas could be expressed. There was no change in the skin or in the circulation of the extremity. Palpation revealed crepitation of tissue and there was abundant gas in the tissues as shown by the x-rays. All of these patients were treated by radical multiple incisions and drainage and the administration of penicillin. All patients in this group recovered.

Hemorrhage from the wound as the first sign of gas gangrene occurred in 6 of the 37 cases. Proximal ligation of the major artery was not effective in any of them. In 5 patients it was possible to control hemorrhage by clamp and ligation of the bleeding points. In 3 patients it was necessary to amputate the extensively damaged extremity.

Sulfadiazine had been given in adequate amounts as a prophylactic agent to 21 of the 37 patients who developed clostridial infection or gangrene. It was used after operation in the treatment of 30 of the patients. Its use produced no significant change in the flora of the wounds. The general condition of the patients did not improve following its use. There was no evidence that sulfadiazine was of value.

The fact that gas gangrene antitoxin had been given prophylactically in the forward areas to only 9 of the 37 patients indicates that surgeons are not convinced of its value. Antitoxin was given therapeutically to 8 patients with no obvious effect on the degree of toxemia.

Thirty of the 37 patients had been treated continuously with penicillin from the time of débridement until arrival at the hospital. Following radical surgery, 31 of the 37 patients were treated intensively with penicillin administered intramuscularly, while 6 patients received injections circumferentially into the muscles of the extremity proximal to the infection. The administration of penicillin had no effect on the degree of toxicity, on the course of the fever, or upon the appearance of the wound. The opinion is obtained that penicillin has no prophylactic or therapeutic value in infections and gangrene due to the *Clostridium welchii*. In all cases clinical improvement was attributed directly to radical surgery. No other measure could substitute for frequent transfusions of whole blood, which were the mainstay of postoperative management.

The opinion is advanced that incomplete débridement without dependent drainage is the most important factor contributing to the development of clostridial infection in war wounds.

JOHN L. LINDQUIST, M.D.

ANESTHESIA

Orton, R. H.: *Anesthesia in Thoracic Surgery*. *Current Res. Anesth.*, 1946, 25: 96.

A review of the literature relating to the physiology involved in thoracic surgery, and to the history of procedures developed to overcome various problems in the administration of an anesthetic for this type of surgery, was made.

Each unit must develop methods suited to the technical abilities and temperaments of both surgeon and anesthetist, to the equipment available, and to the types of operation to be undertaken.

From this review of the progress in thoracic surgery, it is possible to set down certain desirable features that should be fulfilled by this ideal form of anesthesia, viz.

1. The surgeon should have access to the operative area.

2. The tissues of the patient should be adequately supplied with oxygen.

3. Carbon dioxide should be efficiently eliminated.

4. The circulation should not be embarrassed by excessive mediastinal movement.

5. The spread of infected secretions to healthy lung should be prevented.

6. Postoperative atelectasis should be avoided.

7. Recovery of consciousness and cough reflex should be rapid.

8. The use of diathermy should be possible.

Inhalation anesthesia comes nearer the ideal than does spinal or intravenous anesthesia, but even here controversial matters appear, viz.,

1. There is the question as to the desirability of intubating the larynx. Removal of secretions can be performed only when a catheter is present in the larynx. Intubation protects against the dangers of laryngeal spasm.

2. The second point to be considered is positive pressure. The only indication is when a large bronchial fistula exists or is likely to appear.

3. The next controversial matter is the use of controlled respiration. Without voluntary respiration, mediastinal flap and paradoxical respiration are impossible.

4. Finally, the anesthetic agent has to be considered. Cyclopropane is preferred when controlled respiration is contemplated. The chief advantage of ether is that the anesthetic level is more easily maintained, particularly when repeated bronchial suction is necessary.

For extrapleural operations, intubation is not used because of the possible risk of spreading the infection. Controlled respiration is used if needed. Preliminary medication with a barbiturate tends to reduce cardiac irregularities.

For major intrapleural procedures, the method employed is endotracheal inhalation anesthesia with an inflated cuff. Ether-oxygen or cyclopropane-oxygen is administered by a machine capable of positive pressure of 5 to 10 mm. of mercury. Pentothal sodium induction may be used.

When secretions are copious, a catheter fitted with a self-inflating cuff is used and a gas-tight fit is obtained by bringing the catheter through a rubber diaphragm on the mask. A steep Trendelenburg position causes the secretions to gravitate to the face mask. Intermittent suction through the endotracheal catheter is used in addition.

During lobectomies, it has been found advisable periodically to inflate the lobes that are not being

removed at operation. Endobronchial anesthesia has been used for right pneumonectomies. Right endobronchial anesthesia has not been attempted because of the difficulty in avoiding occlusion of the bronchus of the right upper lobe.

During operations for the repair of diaphragmatic hernias, adequate relaxation is one of the first requirements if the abdominal route is chosen. This is obtained by spinal analgesia combined with light cyclopropane anesthesia, or by endotracheal ether-oxygen. If the transthoracic approach is used, minimum diaphragmatic movement is essential. This is best achieved with endotracheal cyclopropane anesthesia and controlled respiration. The diaphragm may be rendered immobile by blocking the phrenic nerve with local anesthetic.

The premedication depends upon whether or not the anesthetist proposes to use controlled respiration. When control is not contemplated, the premedication should be reduced to a minimum so that the respiratory center will not be further burdened. Nembutal and atropine are used to reduce vagal irritability and to lessen cardiac irregularities.

A word of warning must be given as to the amount of intravenous fluid that can be tolerated in the post-operative period. If large amounts are given there is considerable risk of pulmonary edema from overloading of the heart.

MARY FRANCES POE, M.D.

Howkins, J., McLaughlin, G. R., and Daniel, P.: Neuronal Damage from Temporary Cardiac Arrest. *Lancet*, Lond., 1945, 1: 488.

Examples of successful cardiac massage when the heart has stopped beating at operation are now numerous, but permanent success without cerebral damage is governed by the duration of cardiac arrest, the critical limit of which is at most 5 minutes. If this critical period has been exceeded and the heart has started again as a result of resuscitation, neuronal damage is likely to be proportionate to the duration of anoxia. The extent of this damage can be fully assessed only in those infrequent cases in which life lasts for several days or weeks after cardiac disaster.

A case of cardiac arrest in a woman, aged 32, is reported in which the duration of the cessation of heart action was computed to be from 10 to 11 minutes. The heart was successfully restarted by transabdominal massage. The patient survived for 26 days and died of pneumonia and urinary infection. During this time she showed certain neurological features associated with cerebral damage resulting from anoxemia. The electroencephalographic, pathological, and clinical pictures are described and correlated.

JOSEPH GASTER, M.D.

Levy, S., and Conroy, L.: Prothrombin Time and Anesthesia. A Clinical Investigation on the Effects of Ether and Spinal Anesthesia on the Prothrombin Level of the Blood. *Anesthesiology*, 1946 7: 276.

A study was undertaken to establish a relationship between the changed prothrombin level under ether

and spinal anesthesia with procaine, and the incidence of postoperative hemorrhage and postoperative embolism, respectively.

A total of 75 patients were studied. Of these, 50 had received ether anesthesia and 25, spinal anesthesia with procaine.

Prothrombin time determinations with the Smith bedside test were performed five times on each patient. The determinations were made for the first time shortly after admission of the patient to the hospital, the second time after the patient had had the full benefit of his preoperative sedation, the third time under surgical anesthesia, the fourth time in 6 hours after completed anesthesia, and the fifth time 24 hours after the completion of anesthesia.

The results show that ether markedly decreases the prothrombin time of the blood, while spinal anesthesia with procaine does not seem to exert any influence on the prothrombin time. In the group given ether, there was a 25.8 per cent decrease in the prothrombin time as compared to that on admission, and the decrease became even more pronounced (47.5 per cent) when the values of the second test were taken as the basis. In the group under spinal anesthesia, the decrease was only 1.5 per cent as compared to the admission values, and 10 per cent as compared to the values which were obtained after sedation.

The implications of these results in regard to the occurrence of postoperative emboli become clear at once, if they are compared with the findings of

other investigators who have shown that there is also an increase in the number of the circulating red blood cells and platelets and a rise in the hemoglobin values and blood viscosity, a slowing of the circulation time and a shortening of the coagulation time of the blood during ether anesthesia. All of these factors play a dominant role in the causation of thrombosis, and thus are responsible for postoperative embolism. Changes such as these apparently do not happen during spinal anesthesia. On the other hand, since spinal anesthesia does not exert any influence upon the formed elements of the circulating blood, and does not produce a decrease in the prothrombin time of the blood, the possibility of postoperative hemorrhage would appear to be much greater than in the patients given ether.

The results of the fourth and fifth tests show that there is a slow but gradual return of the prothrombin time values to normal.

The effect of drugs used as preoperative and postoperative sedation on the prothrombin time of the blood was also studied. It was found that sedation with barbiturates, notably sodium pentobarbital, causes a lowering of the prothrombin time. Furthermore, it was found that atropine, when given together with morphine, appears to neutralize the decreasing effect of morphine on the prothrombin time, while scopolamine, when given with morphine, does not seem to neutralize the action of morphine on the prothrombin time of the blood.

MARY FRANCES POE, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Howard, C.: Subdural Pneumography. *Am. J. Roent.*, 1946, 55: 710.

The author discusses subdural pneumography, which is the introduction of air into the subdural space so as to separate the brain from the skull and outline the contour of the cerebrum on x-ray films. This procedure demonstrates unknown attachments and abnormal adhesions between the cerebral cortex and the dura and skull. The localization of such attachments is important in jacksonian epilepsy and in post-traumatic cranial conditions.

The surgical technique for this examination is to make a small burr opening in the occipital region of the skull. At the same time from 30 to 60 c.c. of fluid are withdrawn by lumbar puncture to reduce the spinal fluid pressure to about 6 mm. of mercury. A small nick is made in the dura to allow air to enter the subdural space. The spinal fluid pressure rises to its original level and from 15 to 30 additional cubic centimeters of fluid are withdrawn. The dura is closed with a muscle graft. Roentgenograms of the skull are then taken without Bucky grid at a 6 foot tube film distance in various positions to demonstrate the subdural space.

On roentgenograms after air insufflation the cortex is separated from the vault of the skull by a variable space. The negative pressure produced in the subdural space and the gravitational effect on the brain produces this. The corticodural attachments can be visualized and studied. There is wide variation in the attachments. The broadened attachments contain enlarged paeichionian granulations. Under normal conditions there is no connection between the subdural and the subarachnoid spaces. The presence of subarachnoid air in some of these and in encephalographic studies suggests an arachnoidal tear or defect.

Subdural pneumography has demonstrated that the amount of fluid in the subdural space varies from time to time. The procedure of subdural pneumography opens a new field of study for variations in the support of the brain within the skull, the presence of variations of the corticodural attachments, and the presence of a variable amount of fluid in the subdural space.

FRANK L. HUSSEY, M.D.

Doss, A. K.: Translumbar Aortography; Its Diagnostic Value in Urology. *J. Urol.*, Balt., 1946, 55: 594.

During the past 5 years, the author has employed, almost routinely translumbar aortography for the diagnosis of urological conditions. The method has been described elsewhere. The opaque medium used is still the 80 per cent sodium iodide.

In the present article, attention is directed to the renal arterial system.

Renal function. There is no truly adequate test for renal function. It is the author's belief that an organ's function is no better than its blood supply and that, therefore, renal arteriography practically offers a visual estimation of its function. The method is of value especially in demonstrating the condition of the kidney above a completely or partially obstructed ureter. A kidney showing good blood supply may be saved, whereas the presence of poor blood supply would justify nephrectomy. The large hydronephrotic kidney and the kidney filled with a staghorn calculus have often been found by this method to be well worth saving.

Renal neoplasia. Renal arteriography is of little value in the diagnosis of carcinoma. In hypernephroma there is a pooling out of dye scattered in reticulated fashion throughout the neoplastic mass. The intrarenal arteries are characteristically spread out in spiderlike fashion.

Cysts of the kidney. Simple cysts are readily recognized due to lack or lessening of the blood supply, but multiple cysts are difficult to demonstrate.

Retroperitoneal tumor. The method here is of value in establishing a differential diagnosis from tumor of other structures, as for example, spleen, pancreas, etc., and in excluding or convicting the kidney.

Renal ectopia. The various forms of congenital and acquired renal ectopia are clearly demonstrated. The method permits a more scientific approach with respect to nephropexy.

Renal duplication. The diagnosis of renal duplication, suspected in the excretory or retrograde pyelogram, is made relatively simple. The reduced arterial supply of one segment of a duplicated kidney might account for the not infrequently seen pyelonephritis in such cases and might constitute a sound indication for removal of the avascular area of the kidney.

Hypertension. Aortography is the procedure of choice for discovering "Goldblatt hypertension." However, the removal of such a kidney fails to cure the hypertension, for the process is "fixed" also in the other kidney.

Finally, the method may be of value in demonstrating the presence of an aberrant vessel as the cause of hydronephrosis in certain obscure kidney lesions and in renal agenesis. T. LEUCUTIA, M.D.

Levitin, J.: Scout Film of the Abdomen. *Radiology*, 1946, 47: 10.

A scout film of the abdomen especially in acute abdominal conditions may yield information which is of extreme value to the surgeon.

A perforated ulcer may be recognized by the presence of free peritoneal air.

In small bowel distention one may distinguish between paralytic and mechanical ileus. In the latter the loops are greater in the vertical than in the trans-

verse diameter, are generally large, show prominent circular folds, and are subject to vigorous peristalsis as shown on serial films; the distention is confined to the small bowel, whereas a paralytic ileus results in the distention of all the intestinal loops.

Peritonitis may cause mechanical obstruction or paralytic ileus according to the circumstance. There may be an increased density between the loops due to the exudate. A plastic exudate may cause fixation of these loops. This may be recognized on vertical films by the existence of several gas-fluid lines at different levels, whereas otherwise a single gas-fluid level establishes itself. Often the peritoneal fat pad cannot be visualized in peritonitis because of infiltration by exudate.

Local inflammations may cause localized paralytic ileus in which only the adjacent loop of bowel appears to be distended.

Intra-abdominal adhesions may cause temporary (complete or incomplete) mechanical obstruction. In these cases it is important to take the films during an attack.

Acute appendicitis may cause paralytic ileus because of pain or serosal reflexes. The peritoneal fat line may become obliterated. Mechanical obstruction may develop. An abscess may displace the cecum.

Ileocolic intussusception had been recognized by the author on a scout film in 2 instances.

In an obstruction of the colon it is usually possible to differentiate between a gradually developing occlusion which results in a predominantly cecal dilatation (usually caused by carcinoma), and a sudden occlusion caused by a volvulus. In the latter the dilatation may be confined to the twisted section which then can become so large as to fill the abdomen.

There are no conclusive findings on a scout film in gangrene of the bowel.

Finally, absence of dilated bowel loops may point to urinary pathology as the cause of abdominal distress. If no calcified urinary stones are seen a pyelogram is recommended. GERHART S. SCHWARTZ, M.D.

Holmes, G. W., and Schultz, M. D.: *Supervoltage Radiation; A Review of the Cases Treated During an 8 Year Period, from 1937 to 1944, Inclusive*. *Am. J. Roentg.*, 1946, 55: 533.

The authors have analyzed their cases treated with x-radiation generated at 1,200 k.v.p. Their supervoltage unit delivered approximately 52 per cent of the surface dose at a depth of 10 cm., and the point of maximum intensity was about 2 mm. below the skin surface.

Since nearly all of the cases were incurable by standard procedures before x-ray therapy was started, the beneficial effect was evaluated on the basis of increase in life expectancy. Whenever possible, the results are compared with those obtained by older forms of treatment, especially with 200 k.v.p. radiation. The data of Nathanson and Welch (*Am. J. Cancer*, 1936, 28: 40; 1937, 31: 238, 457, 586, 593) have been used for this comparison.

One thousand eight hundred and thirty-seven patients were treated. Of this group, 7.3 per cent were discarded because they were referred back to their local doctor and no attempt was made to follow their progress. Five and three-tenths per cent were lost to observation at varying times and are counted as dead as of the date of the last observation.

The material studied includes tumors of the oral cavity (excluding the tongue and lesions posterior to the anterior pillar), 76 cases; tongue, 60 cases; nasopharynx and nasooaccessory sinuses, 55 cases; tonsils, 38 cases; larynx, 50 cases; lungs, 152 cases; esophagus, 98 cases; stomach, 9 cases; large intestine, rectum, and anus, 33 cases; kidney, 15 cases; urethra, 6 cases; prostate, 52 cases; testicle, 40 cases; bladder, 196 cases; ovary, 89 cases; uterus, 58 cases; cervix, 424 cases; lymphoma, 99 cases; and metastatic disease from various tumors, 143 cases. In addition to these, 23 varieties of benign and malignant lesions totaling 107 cases were treated.

The authors believe that certain selected deep seated localized lesions which in the past have shown some response to high voltage radiation have responded better to supervoltage radiation. The latter seems to offer the patient a slight but definite increase in life expectancy, it makes the patient more comfortable, and it eliminates some of the unavoidably bad effects of lower voltage radiation. There was no evidence to show that a greater number of these tumors can be destroyed by this method of treatment than by other methods.

One of the greatest advantages of supervoltage therapy is the decreased likelihood of serious skin damage when an adequate tumor dose is given. Also, the number of ports required to deliver this dose is reduced. This advantage becomes of considerable importance in the cases in which a cure is expected or life expectancy will be greatly prolonged.

The authors conclude that supervoltage radiation should be encouraged in selected cases of carcinoma of the cervix, carcinoma of the bladder, carcinoma of the lung, embryoma of the testicle, carcinoma of the tonsil, localized lymphoma, Ewing's tumor, and carcinoma of the rectum. R. B. LEWIS, M.D.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Dart, E. E.: Effects of High Speed Vibrating Tools on Operators Engaged in the Airplane Industry. *Occup. M.* 1946, 1: 515.

Disorders of the blood vessels, nerves, muscles, and joints resulting from the occupational use of such vibrating tools as jackhammers and stone chisels have been recognized since 1911 when Loriga described certain peripheral vascular changes occurring in workers using pneumatic devices. Symptoms of temporary ischemia and numbness on exposure to cold followed by flushing, tingling, clumsiness, and decreased sensibility to pain, heat, and cold were observed. Pain was not a prominent symptom except during recovery from the vasospastic attack. Vibration was credited as being the chief causal agent and cold was believed to do no more than to initiate or maintain the response in an already damaged neurovascular system. Numerous subsequent reports had to do with the effects of work with vibrating tools, which Dart classifies into 4 main categories: (1) alteration of the vasomotor responses; (2) injuries to the nerves; (3) injuries to the soft tissue other than the blood vessels and nerves—including muscles, tendons, fascias, and ligaments, and (4) injuries to the bones and joints. These earlier reports, however, had to do with the effects of the older tools which had rates of vibration under 4,000 per minute. The present study is concerned with the effects of high speed electrical and air driven rotary polishing and burning machines which operate at rates of from 10,000 to 50,000, or more, revolutions per minute and are widely used today in the airplane industry.

In this investigation 112 of approximately 1,000 vibratory tool workers were seen because of complaints of pain, numbness, clumsiness, sensation of cold, stiffness, tingling, cramps, or weakness. For purposes of comparison, 112 vibratory tool workers without symptoms and 107 control subjects not exposed to vibration were also observed. Of the patients with complaints, more than half showed no physical changes to account for their symptoms; the remainder exhibited varying signs including swelling, erythema, cyanosis, epicritic sensory loss, atrophy, pallor, and disturbances of motion, such as the inability to tightly flex the fingers, the loss of fine movements, or weakness of grip. Nine patients showed muscle or tendon injuries, including 6 cases of trigger fingers and 3 cases of thickening of the palmar aponeurosis. Eleven patients had gross evidence of neuritis. The diagnosis of peripheral vascular disease could be established beyond reasonable doubt in only 24 patients. The primary involvement affected the fingers, hand, wrist, and forearm, but the remainder of the upper extremity was frequently involved to varying degrees.

To determine the peripheral vascular reactions the author devised a test which he believes is indicative of the state of vascular tone and at the same time is simple enough for the routine examination of large numbers of employees. This test consists of observing at 1 minute intervals the temperature changes on a stem thermometer grasped in the hand following immersion of the part for 5 seconds in water at 35°F. The patients whose temperatures so recorded did not return to the starting level after 15 minutes were arbitrarily determined to have a delayed (vasospastic) response. It was found that in 50 per cent of the control group the temperature had returned to the starting level after 6 or 7 minutes, whereas in 50 per cent of the patients and employees without symptoms the time required was from 9 to 10 minutes. At the end of 15 minutes, 16.8 per cent of the normal individuals still had temperatures below the starting level as contrasted to 33.9 per cent of the employees.

Vasospastic findings in 16.8 per cent of the normal group were similar to the findings of Naide who divided so-called normal subjects into 2 approximately equal groups manifesting low and high vascular tone. The difference in this study and that of Naide as to the proportions of the 2 groups was thought to be due to the arbitrary selection of a standard 15 minute test period.

Workers with tools with vibration rates in excess of 10,000 per minute manifested conditions that differed from those of workers with tools operating at less than 4,000 per minute as follows: (1) symptoms appeared in a matter of days or months after exposure to high speed vibration in contrast to a matter of years after lower speed vibration; (2) pain was usually a major complaint of the high speed tool workers; (3) blanching of the fingers, characteristic in patients exposed to the lower rate of vibration, was absent in those using high speed tools; (4) degenerative bone changes were frequent after use of the older type tools, but were not found in workers using the high speed tools; (5) workers using the lower speed tools usually showed symptoms in the left hand in right handed persons, but those using high speed tools usually presented symptoms in the right hand in right handed individuals; and (6) peripheral vascular disturbances were found to be in the same hand as the symptoms in the earlier reports, but were usually in both hands in individuals using high speed tools.

It is notable that not only the workers complaining of symptoms but all workers exposed to high speed vibration showed a larger percentage of vasospastic reactions than the control group. Frequently the delayed temperature response was the only abnormality that could be demonstrated. Women were found to be more susceptible to vibration effects than men. There was no correlation between

the incidence of peripheral vascular disease and the use of tobacco.

Prophylactic measures recommended are: (1) the elimination of hand work when polishing by wet sand tumbling is possible, (2) the reduction of cold by heating the work rooms and by preventing the tool exhaust from blowing on the hand, (3) the replacement of worn bearings and bent shafts so as to reduce vibration, and (4) the insulation of the tool with felt or rubber to dampen the shock. When there is evidence of injury, transfer of the employee to other work is required. Because of the 16 per cent incidence of delayed reaction in normal persons new employees should be screened, as should tool operators (particularly women), from time to time. Persons with anemia, cardiac disease, or arthritis should not be permitted to work with vibrating tools.

WAYNE CAMERON, M.D.

Erskine, C. A.: An Analysis of the Klippel-Feil Syndrome. *Arch. Path., Chic.*, 1946, 41: 269.

In 1912 Klippel and Feil described the pathological anatomy of absence of the neck in a 46 year old man. The anatomic basis of the syndrome, since known by their names, consists essentially in a congenital fusion and numerical reduction of the cervical vertebrae. Since the original description of this rare condition, most of the communications have been reports of clinical cases of a less extreme type. The 3 characteristic clinical features of the syndrome are shortness of the neck, limitation of movement of the head, and lowering of the hair line.

From the example of the Klippel-Feil syndrome presented and from the case reported in the literature it is concluded that the essential features of the cervical deformity are synostosis of 2 or more cervical vertebrae and flattening and widening of the vertebral bodies. A numerical reduction of the vertebrae is an incidental rather than an essential part of the disorder, as is spina bifida. The latter depends largely on the degree of abnormality of the vertebral bodies. There is evidence that the anomaly has a genetic basis. A number of pathological conditions which have been found in association with the osseous deformity of the syndrome receive an explanation in the light of recent observations in the field of experimental embryology.

JOSEPH GASTER, M.D.

Paxson, N. F., Golub, L. J., and Hunter, R. M.: Crush Syndrome. *J. Am. M. Ass.*, 1946, 131: 500.

Although the syndrome of urinary suppression following crushing injuries was first described in 1917, recent bombings have stimulated the most interest in this subject. In the order of occurrence, the crush syndrome is characterized by initial tissue damage, shock which may be moderate or quite severe (sometimes it is absent), oliguria or anuria, uremia, and possibly death.

Microscopic examination of the kidneys shows the tubules to contain casts and granules of blood pigment, with epithelial degeneration of the second portion and occasionally of Henle's loop. The glomeruli

remain undamaged apparently. Since the chief changes are tubular, the dilute, highly acid urine, low in urea and high in chlorides, is explained.

Several theories have been postulated to explain the renal damage: ischemia, tubular obstruction, and the release of substances which are toxic to tubular epithelium. The last of these was suggested by Young in an extensive review of obstetric hemorrhage concomitant with urinary suppression, and is believed to be the most plausible by the authors.

Three cases of crush syndrome, 1 occurring with a retroplacental hemorrhage, 1 with a ruptured uterus, and 1 with a twisted ovarian cyst, and all with oliguria are presented. All had extensive extravasation of blood into the surrounding tissue. This is the first time that this syndrome has been described with an ovarian cyst. Two patients showed minimal shock signs while 1 patient experienced severe shock although she did not die. Two recovered, but the one with the retroplacental hemorrhage succumbed on the twelfth postpartum day.

It is suggested that this syndrome is more frequent than is now recognized, and not only is worth further investigation, but may be the explanation for some previously obscure obstetric fatalities.

C. FREDERICK KITTLE, M.D.

Kemp, F. H., and Vollum, R. L.: Anaerobic Cellulitis Due to Actinomyces, Associated with Gas Production. *Brit. J. Radiol.*, 1946, 19: 243.

The authors report a case of anaerobic cellulitis in a diabetic woman, 47 years of age, which started with infection of a corn on the big toe. The infection remained localized to the toe for a month and then, 4 days before hospitalization of the patient, it spread to the dorsum of the foot, which was gangrenous at the time of admission.

In spite of intensive treatment for the diabetes and the administration of 16,000 units of penicillin intramuscularly every 3 hours, the cellulitis spread upward rapidly and reached the distal thigh within 10 days after admission.

X-ray films revealed bubbles of gas in the subcutaneous tissues of the dorsum of the foot, calf, and lower third of the thigh. Smear from the foot showed actinomyces and a culture revealed a mixed growth of the *Staphylococcus aureus*, the *Bacterium coli*, and the *Pseudomonas pyocyanea*. Amputation was done through the middle third of the thigh; the amputation stump excreted much foul smelling material on drainage, and the patient died 5 days after operation.

Cultures of the pus obtained by sterile technique from the subcutaneous tissues of the upper calf immediately after amputation yielded actinomyces, which produced gas in subculture on Robertson's meat medium. Further examination of the specimen showed that the severe purulent cellulitis was confined largely to the subcutaneous tissues; there was a little spread into the chief fascial planes, but no infiltration was seen in the muscle substance.

LILIAN DONALDSON, M.D.

Pope, C. E.: A New and Successful Closed Operative Procedure for Pilonidal Sinus; Gluteus Maximus Mobilization; A Sliding Muscle Graft Procedure. *Arch. Surg.*, 1946, 52: 701.

The author reports a closed operative procedure for pilonidal sinus, which employs a sliding gluteal muscle graft. The technical details of the operation and the surgical principles it entails are described. In a series of 130 closed operations, 92 gluteus maximus sliding grafts were successfully made. The operation is applicable in all cases of pilonidal sinus excepting those in which there is involvement of the spine or bones, and it successfully overcomes the numerous disadvantages of other types of pilonidal sinus operations, whether they be closed, open, or partially closed.

require protection; (5) a greatly increased therapeutic effect from sulfonamide and penicillin therapy by the blood stream route; and (6) the feasibility of block excision.

The initial step in the operative procedure, block excision, is illustrated in Figure 1. For closure it is sufficient, in practically all cases, to mobilize the gluteus muscle on one side. The base of the wound is palpated to determine the rolling edge of the sacrum and the gluteus attachment. An incision is made through muscle and fascia at the edge of the sacrum, following which a blunt cleavage separation, that is relatively bloodless, can be carried laterally as far as necessary for supple closure of the wound. It is then possible to cover the whole sacral and coccygeal area with a firm sliding layer of muscle

Fig. 1. Semischematic illustration demonstrating block excision of pilonidal sinus.

Mobilization of a gluteus maximus muscle flap and its employment as a graft has the following advantages: (1) adequate replacement of dead space by a muscle sliding graft; (2) freedom from tissue tension by muscle mobilization; (3) increased blood supply, increased rapidity of tissue healing and enhanced ability to combat infection by reason of the muscle graft and supple tissues, free from tension; (4) a more adequate protective pad of tissue covering an exposed defect in an otherwise relatively avascular area, where exposed sacrococcygeal bone and fascia

tissue with its overlying skin and fat. Deep closure is effected by two sets of removable wire suture, and the skin is closed with silk. Following this procedure, a pressure dressing is applied, with binding of the buttocks. No dressings are necessary until the eighth day, when the wire sutures are removed. After the tenth day gradually increased activity is permitted.

The author believes that the results in his series of cases indicate adoption of the procedure.

JOHN L. LINDQUIST, M.D.

Calvacabo, G.: Malignant Myoma; an Anatomopathological Contribution (*Mioma maligni; contributo anatomo-patologico*). *Tumori*, Milano, 1943, 29: 267.

Two cases of malignant myoma are reported. The first was that of a 51 year old male who suffered an injury to the perineal region (on falling astraddle a tree limb), and a year later exhibited a tumefaction adherent to the end of the coccyx and protruding slightly into the rectum. The tumor was rather soft and adherent to the skin and rectal mucosa. Roentgen examination showed decalcification and alteration of the adjoining coccyx. The neoplasm was not removed but the biopsy specimen was pronounced a myoma malignum by Businco.

The second case, also pronounced a malignant degeneration of a uterine myoma by Businco, was found in the extirpated uterus of a 60 year old woman. This second tumor was not so polymorphous, undifferentiated or atypical (in contradistinction to the first) that its leiomatous character could not be recognized.

The author concludes from his own personal observations and from a study of the literature that all the various types of myoma are merely degrees of a general anaplastic process, ranging from that degree wherein the original tissue (striated or nonstriated muscle tissue) is sufficiently preserved in the tumor itself as to be recognizable (as in a rhabdomyoma or leiomyoma) to that in which polymorphous and undifferentiated tissues closely resemble the histological picture presented by the sarcomas.

JOHN W. BRENNAN, M.D.

Papanicolaou, G. N.: The Diagnosis of Cancer. *J. Am. M. Ass.*, 1946, 131: 372.

The apparent potentialities of studying the exfoliated cells in various secretions of the body have not been fully appreciated probably because of an inefficient and inadequate technique. Good fixation and good staining of the cancer cells are of paramount importance in this cytological method of diagnosis.

The diagnostic value of the smear test is based on the constant exfoliation of malignant neoplasms with a free surface.

Smears from the vaginal secretion, sputum, and gastric, duodenal, thoracic, and peritoneal fluid can be prepared.

Among the advantages of this method one should mention that: (1) it is simple and inexpensive, (2) it is reliable in the hands of experienced men, (3) it permits the early recognition of incipient cases or of hidden carcinomas such as carcinomas *in situ*, (4) it can be carried out on a large scale as a screening method, (5) it does not conflict in any way with other well established methods of pathological diagnoses, (6) it may eventually reveal the presence of cancer when biopsy has failed, although it may occasionally fail to show an existing cancer discovered by biopsy, and (7) it is of unique value in following up the result of operative procedures or the progress of irradiation or other therapy.

The main disadvantages are that (1) the criteria of the method are not yet clearly outlined and need to be further standardized, (2) the type and origin of the malignant cells are not always clear, (3) the grade of malignancy is not revealed, (4) no information is given as to the mitotic activity of the malignant growth or as to its relationship to the adjoining normal tissues, and (5) the average time required for the examination of a smear is somewhat longer than that required for examination of a pathological section.

JOSEPH K. NARAT, M.D.

Hueper, W. C.: Occupational Cancer. *J. Am. M. Ass.*, 1946, 131: 738.

The term "occupational cancer" is applied to malignant tumors which originate in persons during the course of, and as the result of, the regular and usually prolonged exercise of certain occupational activities which entail contact with some exogenous physical or chemical carcinogenic agent acting in proper intensity.

With the advent of the modern industrial era, the soot cancer of the English chimney sweeps and the lung cancers of the cobalt and uranium miners in Schneeberg and Joachimsthal were recognized as of occupational origin. The urinary bladder tumors in workers in the aniline dye industry and the cancer resulting from contact with radioactive substances and roentgen rays were added to the growing list of occupational cancers. Definite proof of carcinogenic properties has been obtained for arsenic, tar, pitch, soot, crude mineral oil, crude paraffin oil, anthracene oil, shale oil, some fuel and lubricating oils, creosote, benzene, aromatic amines, and rays from radioactive substances. The exposure time necessary for eliciting cancerous reactions in exposed workers varies greatly with the type and potency of the carcinogenic agent, the intensity of the exposure, and the susceptibility of the individual. The range is from 6 months to 3 to 4 decades, while the average time is from 5 to 15 years.

The rapid increase in the number of recognized and suspected agents causing industrial cancer which has occurred during the last 40 years makes it more likely that new and heretofore unsuspected carcinogenic agents of an industrial nature will be discovered during the coming years. Such a development is foreshadowed by the observations made recently that cancers of the liver develop in mice exposed to carbon tetrachloride, a commonly used organic solvent, and that cancers of the lung develop in mice which inhale ethyl carbonate (urethane), which is employed for anesthetic purposes.

Fourteen comprehensive recommendations are made. Among these is the suggestion for a nation wide survey by skilled investigators, representing management, industrial physicians, members of the Public Health Service and of departments of industrial hygiene, to determine the actual scope of the problem of industrial cancer. Lastly, an institute for the study of occupational cancer should be founded and should be

attached to or co-ordinated with one of the large existing cancer research centers in order to provide for proper integration of the results obtained by such investigations with those obtained by cancer research in general. Such an organization would serve industry for consultative and investigative purposes on matters of occupational cancer.

EDMUND A. GORVETT, M.D.

Bogart, F. B.: Leucosarcoma. *Am. J. Roentg.*, 1946, 55: 743.

Sternberg in 1908 first described a clinical entity characterized by mediastinal enlargement and a terminal blood picture classified as acute lymphatic leukemia. Study of enlarged superficial lymph nodes is reported as lymphosarcoma. At autopsy there was lymphoblastic infiltration of the thymus, and an enlargement of the liver, spleen, kidneys, and other organs.

As the thymic enlargement frequently produces the first symptom, shortness of breath, the chest roentgenogram often is the first procedure used for examination. Therefore, the radiologist should be aware of this entity so as to evaluate the x-ray findings properly and possibly suggest the clinical diagnosis before blood changes occur.

Leucosarcoma may occur at any age from 6 to 70, with one-third of the cases being found between the ages of 21 and 30. There is no sex predominance. Not all authors agree completely with Sternberg's description. Flashman and Leopold reviewed 107 cases and found only 60 with primary invasion of the thymus. Some reports in the literature describe a similar syndrome in which other glands than those in the mediastinum are primarily involved. Evans and Leucutia believe that if more patients with lymphosarcoma would live longer, they would probably show the terminal leucemic blood picture. Isaacs believes the condition is primarily a blood dyscrasia and the predominant blood cell—the leucosarcoma cell—must be differentiated from lymphoblasts and other immature blood cells by its staining characteristics.

The blood picture may be normal when first seen. The symptoms vary considerably and include: malaise, weight loss (usually slight), slight elevation of the temperature, bleeding (petechiae, hemoptysis, hematuria, epistaxis, hematocremesis, gross bleeding from the mucous membranes, and retinal hemorrhages), joint pains, chest pains, cough, dyspnea, herpes, toxic erythema multiforme, diplopia, and local edema.

There is considerable diversity of opinion as to the origin of the invading cell. Sternberg believed it was a large lymphoblastic type of blood cell. Some believe the thymus is the point of origin, while Margolis and others believe the thymus is invaded along with other organs and that the cells do not represent hyperplasia of the thymic gland cells.

The early opinion that roentgen therapy precipitated the leucemic phase has now been entirely disproved. Roentgen therapy is indicated when the

mediastinal enlargement or other glandular masses produce circulatory or respiratory embarrassment. If the patient is seen before the leucemic phase with a large mediastinal mass blocking adequate circulation to the head and neck with gross swelling of the face and neck, the response to roentgen therapy is often prompt and dramatic. Gross reduction in the tumor mass with relief of the edema and distress within from 24 to 48 hours after the administration of from 200r to 400r should lead the radiologist to suspect that he is dealing with a leucosarcoma. The course of the disease is rapid and is usually not affected by roentgen therapy, ending fatally in a few weeks or months.

The author presents 2 complete case reports, including blood studies and autopsy findings which conform to Sternberg's description.

ROBERT R. BIGELOW, M.D.

Carp, L.: Basic Principles in Geriatric Surgery. *Ann. Surg.*, 1946, 123: 1101.

This article presents briefly some of the more pertinent principles in geriatric surgery, the importance of which is emphasized in the latest census figures. Between 1930 and 1940, the life span of people over 65 increased 35 per cent as compared to a 7.2 per cent increase in the general population. Geriatric surgery can "add life to years and years to life."

Since the opening in 1930 of a modern, well equipped, 1,500 bed municipal hospital in New York, for research of the causes, prophylaxis, and management of chronic illnesses, 450 major operative procedures have been performed on people over 60 years of age. They were all bad risks, particularly since most of them had been neglected for a considerable time prior to surgery. This, the author believes, accounted for the high mortality rate of 22.6 per cent, but he clearly shows that this appalling figure is not a true index as to the ability of the aged to withstand surgery presently. Recent advances in medicine and surgery have outlasted the maxim that old age itself precludes surgical intervention.

It is difficult to establish a line at which old age begins, but biologically it depends upon the degree of degeneration present, which process usually is slow progressive, and persistent. All tissues and organs in an individual do not necessarily age synchronously. Senility implies physical defects and degenerative conditions accompanied by social maladjustment and impairment of the intellect, emotions, and sustained effort.

Numerous factors must be considered judiciously in evaluating the risk of operating on the aged, and it is emphasized that experienced surgical judgment is of no minor importance in this connection. The diminished reserve in the aged must be ascertained and one must not lose sight of the fact that conservatism is often hazardous and fatal. Diseases of the cardiovascular and renal systems, as well as debilitation and dehydration, frequently complicate the picture and, needless to say, must be discerned and

If the patient is seen before the leucemic phase with a large mediastinal mass blocking adequate circulation to the head and neck with gross swelling of the face and neck, the response to roentgen therapy is often prompt and dramatic. Gross reduction in the tumor mass with relief of the edema and distress within from 24 to 48 hours after the administration of from 200r to 400r should lead the radiologist to suspect that he is dealing with a leucosarcoma. The course of the disease is rapid and is usually not affected by roentgen therapy, ending fatally in a few weeks or months.

The author presents 2 complete case reports, including blood studies and autopsy findings which conform to Sternberg's description.

ROBERT R. BIGELOW, M.D.

Carp, L.: Basic Principles in Geriatric Surgery. *Ann. Surg.*, 1946, 123: 1101.

This article presents briefly some of the more pertinent principles in geriatric surgery, the importance of which is emphasized in the latest census figures. Between 1930 and 1940, the life span of people over 65 increased 35 per cent as compared to a 7.2 per cent increase in the general population. Geriatric surgery can "add life to years and years to life."

Since the opening in 1939 of a modern, well equipped, 1,500 bed municipal hospital in New York, for research of the causes, prophylaxis, and management of chronic illnesses, 450 major operative procedures have been performed on people over 60 years of age. They were all bad risks, particularly since most of them had been neglected for a considerable time prior to surgery. This, the author believes, accounted for the high mortality rate of 22.6 per cent, but he clearly shows that this appalling figure is not a true index as to the ability of the aged to withstand surgery presently. Recent advances in medicine and surgery have outdated the maxim that old age itself precludes surgical intervention.

It is difficult to establish a line at which old age begins, but biologically it depends upon the degree of degeneration present, which process usually is slow progressive, and persistent. All tissues and organs in an individual do not necessarily age synchronously. Senility implies physical defects and degenerative conditions accompanied by social maladjustment and impairment of the intellect, emotions, and sustained effort.

Numerous factors must be considered judiciously in evaluating the risk of operating on the aged, and it is emphasized that experienced surgical judgment is of no minor importance in this connection. The diminished reserve in the aged must be ascertained and one must not lose sight of the fact that conservatism is often hazardous and fatal. Diseases of the cardiovascular and renal systems, as well as debilitation and dehydration, frequently complicate the picture and, needless to say, must be discerned and

corrected preoperatively if possible. **Clinical syndromes** may be masked in old age and **one must be vigilant**. Frequently, the absence of fever, pain, and leucocytosis is a common finding in peritonitis, and, clinically, chest findings may be minimal even in the presence of a diffuse bronchopneumonia. Certainly, this stresses the need for adequate consultation. Elective surgery should be postponed during hot, humid weather. Coronary sclerosis per se is not a contraindication to operation if decompensation is not present. Acute occlusion after operation is infrequent.

Provided the risk is not too great, the indications for operative intervention are similar to those of any age group. In the aged, these indications generally result from complications connected with the degenerative processes, whether inflammatory, metabolic, or neoplastic.

Shock is insidious and most hazardous, and correction may be in vain. Precise technique is mandatory and frequently "staging" of an operation is well advised. Supportive measures during a prolonged procedure are imperative. A major factor in the increased success of geriatric surgery is the improvement in anesthesia. The author stresses the role which crymal anesthesia plays in amputations of the lower extremity.

Old people recover more quickly from an operation and have fewer wound disruptions than is generally realized. Early ambulation, in selected instances, reduces the *bleu noire* of geriatric surgery, namely, pneumonia, circulatory failure, and pulmonary embolism. Medicinal depression should be avoided for the same reasons. Old people often must be handled with patience and tact. Psychiatric consultation and therapy may be required. DAVID H. LYNN, M.D.

SUBJECT INDEX—ABSTRACTS—VOLUME 83

- ABDOMEN**, Inguinal hernia and its repair, 42; post-appendectomy interstitial inguinal hernia, 42; par-
oysmal abdominal pain, 51; acute pancreatitis and
splanchic block, 153; last "hate", 155; early results in
short series of cases of gunshot wounds of, 156; splen-
ectomy, its historical background, indications and ra-
tionale, and comparison of reported mortality; collec-
tive review, 209; supposed difference in defensive
power of peritoneum in distinct sectors of, 247; gun-
shot wounds of, 257; studies of wounds of, and thorax
produced by high velocity missiles, 291; intestinal ob-
struction following abdominal battle wounds, 355;
probable case of traumatic appendicitis, 357; Fowler's
position, 364; inguinal herniorrhaphy from intra-ab-
dominal perspective; retention of sac and intact ex-
ternal ring and means for proving adequacy of repair,
457; apoplexy of, 471; trauma to, 472; uncomplicated
prolapse of ovary as cause of acute pain in, 476; ovar-
ian hemorrhages with attention to intra-abdominal
hemorrhages from corpus luteum, 477; amebiasis of
skin and subcutaneous tissue; report of 3 cases with
amebic ulceration of wall of, and thoracic wall follow-
ing intervention, 514; fibroma of left rectus abdominis
muscle in male, 559; piezoelectric crystal measure-
ments of pressure changes in, of deeply anesthetized
animals during passage of high velocity missile, 568;
scout film of, 605
- Abnormalities**, Symposium; nonmalignant conditions of
esophagus, 349; ectopia vesicae, 376; congenital, in
infants following infectious diseases during pregnancy,
with especial reference to rubella; third series of cases,
483
- Abortion**, Genital infarcts after, 264; therapeutic, in gen-
eral hospital, 576
- Abscess**, Putrid lung, 35; delayed post-traumatic brain,
233; studies in lung, 444; pyogenic liver, 256; craniot-
omy and total dissection as method in treatment of, of
brain, 334; secondary epithelization of cavities of
chronic lung, 341; surgical treatment of, of middle lobe
of right lung, 341; analysis of brain, observed during
past 30 years, 447; of lung; report of 46 operated cases,
452
- Accidents**, Transfusion, 500
- Achalasia** of esophagus following depressed fracture of base
of skull, 233
- Acid** burns of eye, 115
- Acidophil** paste, Treatment of wounds with, and acidophil
serum, 187
- Actinomyces**, Anaerobic cellulitis due to, associated with
gas production, 608
- Actinomycosis**, Temporomaxillary, caused by anaerobic
actinomycetes of Wolff-Israel type cured by combination
of sulfa drugs and roentgen therapy, 541
- Adenocarcinoma** of urachus involving urinary bladder, 472
- Adenolymphoma** of parotid and submaxillary salivary
glands, 546
- Adenoma** of islets of Langerhans and pregnancy, 567
- Adhesives**, Synthetic, in treatment of wounds of liver and
other surgical conditions, 195
- Adrenal** cortex, Small adenomas of, in hypertension and
diabetes, 63
- Adrenal** glands, Effect of pituitary adrenotropic hormone
on cholesterol and ascorbic acid content of, in rat and
guinea pig, 102
- Adrenitis**, Report of case of acute hemorrhagic, 63
- Adrenogenital** syndrome of girl with pseudohermaphro-
ditism, 159
- Aerobematoma** of sinuses, 327
- Aerotitis**, Use of radium in control of, in Army Air Forces,
201
- Age**, Basic principles in geriatric surgery, 611
- Agranulocytosis**, Treatment of hyperthyroidism with thi-
ouracil, with reference to toxic reactions; collective re-
view, 313
- Air** hygiene in dressing rooms for burns or major wounds,
397
- Airplane** industry, Effects of high speed vibrating tools on
operators engaged in, 607
- Albumin**, Concentrated human, in treatment of shock, 570
- Amebiasis**, Of urinary tract, 492; of skin and subcutaneous
tissue; report of 3 cases with amebic ulceration of ab-
dominal and thoracic wall following intervention, 514
- Amino** acids in production of plasma protein and nitrogen
balance, 307
- Amputation**, Exarticulation of lower extremities for malig-
nant tumors, 588; retracted and short, stump of leg;
treatment and prosthesis, 589; technique of Syme,
590; causes of, in battle casualties with emphasis on
vascular injuries, 600
- Amyloid** nephrosis, Early, following compound bone in-
juries, 164
- Anaerobic** microbes, Effect of penicillin on septicemia
caused by, 401
- Analgesia**, Continuous caudal and spinal, in cesarean sec-
tion, 60, sepsis and asepsis in spinal, 194; continuous
spinal, in cesarean section, 576
- Anaphylaxis**, Fatal anaphylactic shock, 510
- Anatomy**, Contribution of, to war, 93
- Anesthesia**, Continuous spinal and caudal analgesia in ce-
sarean section, 60; complications in, and their manage-
ment, 85; ether convulsions; discussion and presenta-
tion of case, 85; curare; misconceptions regarding the
discovery and development of present form of drug,
86; curare and nitrous oxide, for lengthy operations,
86; experiences with endotracheal ether-air for intra-
thoracic surgery, 87; anesthetics, 193; procedures
used in general hospital in communication zone with
analysis of 2,000 anesthetics, 193; continuous lumbar,
with dilution technique, 193; physiological and clinical
action of curare, 194; sepsis and asepsis in spinal anal-
gesia, 194; frontiers of, 205; hypotension and spinal;
veritol test, 206; new lethal dose of curare; pathology
produced by large doses, 206; treatment of acute
arrhythmias during, by intravenous procaine, 206;
technique of lobectomy; individual ligation of parts of
pedicle, 346; spinal, and chloroform; comparison of
mortality, 401; refrigeration in orthopedic and trau-
matological surgery, 499; of recent injuries of jaw and
face, 504; histamine-like action of curare and tubo-
curarine injected intracutaneously and intra-arterially
in man, 505; milestone in; d-tubocurarine chloride,
505; management in reconstructive surgery of man-
dible, 542; continuous spinal analgesia in cesarean sec-
tion, 576; in thoracic surgery, 602; prothrombin time
and; effects of ether and spinal, on prothrombin level
of blood, 603
- Aneurysm**, Arteriovenous, of scalp and face, 113; of hepatic
artery, 152; true, of renal artery, 486; treatment of
syphilitic, by cellophane wrapping, 555
- Angiography**, Evaluation of usefulness, 389

- Angioma of kidney, 165
 Ankle, Roentgenographic examination of, joint in malleolar fractures, 197; trimalleolar fractures of; conservative method of treatment, 386
 Ankylopoietic spondylarthritis, Dechterew's disease from roentgenological point of view, 198
 Ankylosis of temporomandibular joint, 113
 Anoxemia, Effects of artificial ductus arteriosus on experimental cyanosis and, 312
 Anoxia, Histopathological effect of, on central nervous system, 22
 Antibiotic agents, Summary of surgical aspects of certain sulfonamides and; collective; review, 1; effect of some, on pathogenic fungi, 103
 Anticoagulants, Challenge of thrombosis and embolism of blood vessels and clinical use of, 286, medication with dicoumarin, 289
 Anus, Study of anorectal cancer, 256; imperforate, 359
 Aorta, Traumatic arteriovenous fistula involving abdominal, and inferior vena cava, 500, thrombotic obliteration of bifurcation of, 594; case of obliteration of bifurcation of (Leriche's syndrome), treated by resection of bifurcation, 595
 Aortography, Translumbar; its diagnostic value in urology, 605
 Aponeurosis, Rupture in, of shoulder joint; its treatment, 172
 Apoplexy, Abdominal, 471
 Appendectomy, Pseudomyxoma of peritoneum, 248
 Appendicitis, Diagnosis of acute, in presence of diarrhea, 357; probable case of traumatic, 357; in children; review of 1,000 cases taken from records of Children's Hospital, Los Angeles, 462
 Appendix, Acute volvulus of, 255; carcinoid of ileocecal, 254; reflections on retrocecal; unusual complication, 254
 Aqueduct of Sylvius, Lesions of, 22
 Aqueous humor, Penicillin in, 16
 Arm, Repair of surface defects of upper extremity, 396
 Arrhythmias, Treatment of acute, during anesthesia by intravenous procaine, 296
 Arteries, Arteriovenous aneurysms of scalp and face, 173; aneurysm of hepatic, 152; vascular injuries of extremities in battle casualties, 170; surgical management of occlusion of, 180, results following bands and ligatures on human internal carotid, 180; laws of arterial thrombosis, 183; thrombosis; experimental and clinical conditions, 283; battle injuries of, in World War II, 390; true aneurysms of renal, 486, traumatic arteriovenous fistula involving abdominal aorta and inferior vena cava, 500; histaminelike action of curare and tubocurarine injected intracutaneously and intra-arterially in man, 503; preservation of vein in operations for arteriovenous fistula, 594; periarteritis nodosa; clinical manifestations and postmortem findings; 6 cases, 595; surgery of innominate, 596
 Arteritis, Cranial, critical evaluation of syndrome of temporal; report of case, 77
 Arthritis, Muscle-flap transplant for relief of painful monoarticular (aseptic necrosis) of hip, 384
 Arthrosis in knee after meniscectomy, 495
 Ascorbic acid, Effect of pituitary adrenotropic hormone on content of cholesterol and, in adrenal glands of rat and guinea pig, 102; late secondary tonsillar hemorrhage; studies of, 547
 Asepsis, Sepsis and, in spinal analgesia, 194; hospital blankets as source of infection, 398; treatment of hospital blankets with oil emulsions and bactericidal action of "fixanol C" (cetyl pyridinium bromide), 398
 Asphyxia of newborn infant, 577
 Atlas, Subacute osteitis of, following suppuration of mastoid or of lateral region of throat, 495
 Atresia, Congenital, of common bile duct, 564
 Auditory apparatus, Theory of mechanism of, 324
 Autopsy, Causes of acute peritonitis observed at, 247; nasopharynx; study of 140 specimens, 546
 Autotransplantation, Multiple peritoneal, of splenic tissue following traumatic rupture of spleen, 471
 Azotemia, Study of, observed after severe burns, 511
BACILLUS proteus, Treatment of infections with NU-455, 276
 Back, Diagnosis of lumbar intervertebral disc protrusions, 123; lumbar herniations of intervertebral discs; value of surgical removal for naval personnel, 123; translumbar aortography; diagnostic value in urology, 605
 Bacteriology, Of septic fingers, 83; penicillin in ophthalmology; bacteriological, experimental, and clinical evidence of its value; 125 cases, 227; and histology of healing burns with inquiry into significance of local infection, 293; of peptic ulcer and gastric carcinoma, 561
 Banti's disease, Splenectomy; historical background, indications and rationale, and comparison of reported mortality; collective review, 209
 Basedow's disease, Acute hyperthyroid crises, physiopathological study, 230
 Bauhin's valve, Value of roentgenology in diagnosis of tuberculosis of, 253
 Bechterew's disease from roentgenological point of view, 198
 Betel, Chewing of, among natives of southwest Pacific Islands; lack of carcinogenic action, 309
 Bile ducts, Congenital cystic dilatation of common, 49; syndrome of sphincter of Oddi, 363; choledochus cyst, 468; congenital atresia of common, 564
 Biliary tract, Pancreatitis; anatomic study of pancreatic and extrapancreatic, 154; study of dyskinesia of, 257; chronic relapsing pancreatitis; 29 cases without associated disease of, or gastrointestinal tract, 469
 Bilirubin production by human organism and its significance in pathogenesis of jaundice, 48
 Bilirubinemia, Hereditary nonhemolytic, 361
 Bladder, Some improvements in technique of ureterocystostomy, 65; study of ureters in obstructions of neck of, 165; etiology of acquired fibrosis of neck of, 166; malacoplakia of, 166; diverticulum of; diagnosis and treatment, 271; cystometry in study of traumatic neurogenic, 376; ectopia vesicae, 376; adenocarcinoma of urachus involving urinary, 472; late erosion of shell fragment into, 483; wounds of urinary, 579; treatment of carcinoma of, for past 5 years; closed method of treatment, 579
 Blankets, Treatment of hospital, with oil emulsions and bactericidal action of "fixanol C" (cetyl pyridinium bromide), 398; hospital, as source of infection, 398
 Blast, Effect of, on human ear, 117; medical aspects of, 496
 Blastomycosis, Uveal, 115; brief review of literature and report of case involving meninges, 399
 Blood, Investigations of postoperative shock; hemocoagulation, plasma protein, and electrolytes of, after gastrectomy, 45; primary congenital and secondary acquired splenic panhematopenia, 50; derivatives of, and substitutes in obstetric and gynecologic practice, 54; decrease of serum cholesterol ester in hemolytic disease of newborn, 60; acute hematogenous osteomyelitis in infancy, 71; Rh factor; survey of subtypes of white Australians, 79; irregular hemagglutinins after transfusion, 79; studies of effects of radioactive sodium and of roentgen rays on normal and leucemic mice, 89;

- sludged, in traumatic shock; microscopic observations of precipitation and agglutination of blood flowing through vessels in crushed tissues, 93; relation of certain fractions of plasma globulins of, to coagulation defect in hemophilia, 181; determination of groups of, use of rabbit immune serum, 182; transfusion of 2,386 liters of, 183; results of roentgen treatment of leukemia, 303; treatment of hyperthyroidism with thiouracil, with reference to toxic reactions; collective review, 313; hereditary, nonhemolytic bilirubinemia, 361; disorders of, associated with pregnancy, 370; prothrombin level of peripheral, and sternal marrow, 392; some newer concepts of natural derivatives of hemoglobin, 393; alterations in normal and decapsulated kidneys caused by transfusion of heterogenous, 394; observations on capillary and venous, in traumatic shock, 408; prolongation of life with prevention of leukemia by thymectomy, 415; experiences in subtotal resection of pancreas in hypoglycemia, 470; individual differences in, in relation to pregnancy, with reference to pathogenesis of preeclamptic toxemia, 484; transfusion accidents, 500; transfusion of, to recipients with "cold" agglutinins, 501; study of azotemia observed after severe burns, 511; behavior of hematological picture in commotio cerebri, 548; acute hematogenous osteomyelitis treated with penicillin, 584; prothrombin time and anesthesia; clinical investigation on effects of ether and spinal anesthesia on prothrombin level of, 603
- Blood pressure, Sympathectomy for hypertension, 337**
- Blood vessels, Venospasm; part in producing clinical picture of Raynaud's disease, 76; cranial arteritis; critical evaluation of syndrome of "temporal arteritis" with report of case, 77; new findings with respect to nature, prevention and treatment of thrombosis and embolism, 77; polyarteritis nodosa; report of 11 cases with review of recent literature, 77; vascular mechanisms of terminal shock, 95; vascular injuries of extremities in battle casualties, 179; challenge of thrombosis and embolism of, and clinical use of anticoagulants, 286; surgical treatment of vascular anomalies of premotor area producing epilepsy, 333; angiography; evaluation of usefulness, 389; traumatic arteriovenous fistula involving abdominal aorta and inferior vena cava, 500; physiology and immobilization and local effects of heat and cold, 508; treatment of syphilitic aneurysms by celophane wrapping, 555; vasospastic disease (morbus vasospasticus), 594; thrombotic obliteration of bifurcation of aorta, 594; causes of amputations in battle casualties with emphasis on vascular injuries, 600**
- Bone, Xanthoma or lipid granuloma of temporal; Hand-Christian-Schuller syndrome, 117; control of fragments of, in maxillofacial surgery, 118; early amyloid nephrosis following compound injuries of, 164; incidence of osteochondrosis, 171; skeletogenous tumors of mammary gland, 239; penicillin for osteomyelitis, 278; brucellosis spondylitis, 278; reflex hyperemic deossification regional to joints of extremities, 308; aspects of osseous growth and calcium metabolism in case of exophthalmic goiter in child of 6 years, 328; study of pathogenesis of idiopathic osteopsathyrosis, 382; embolism of marrow of, following fracture, 387; osteoarticular tuberculosis and trauma, 382; experimental observations on use of absorbable and nonabsorbable plastics in surgery of, 388; deformities following surgical epiphyseal arrest, 388; influence of estrogens on crystal structure of, as revealed by x-ray diffraction studies on femora of mice, 416; use of cancellous, in repair of defects about jaws, 440; treatment of acute osteomyelitis with penicillin, 493; penicillin in chronic osteomyelitis, 493; malignant osteogenic osteoblastoma with myeloplax, 494; pulsating benign giant cell tumors of; report of case and review of literature, 494; union of intramedullary fixation, 495; significance of minor injuries of, 507; unilateral hyperplasia of mandibular condyle, 542; development of squamous cell carcinomas in sinus tracts of chronic osteomyelitis, 592**
- Bones, March (fatigue) fractures of long, of lower extremity and pelvis, 75; synostosis of pubic symphysis; anatomic and clinical study, 161; results of stabilizing operations on, in paralytic leg, with or without transplantations of tendons, 173; intramedullary pinning of diaphyseal fractures, 279; intramedullary nail technique for treating fractures of long, according to method of Kuentscher, and indications, 387; new concept of treatment of congenital pseudarthrosis of tibia, 496; treatment of fractures of carpal scaphoid; report of 64 cases, 498; orthopedic and rehabilitation service of Royal Air Force, 498; osteomyelitis involving sphenoid, 541**
- Bracht's maneuver, Experience with, in delivery in cases of pelvic presentation, 264**
- Brain, Glioma of retina and of, in collateral lines in same family; genetics of glioma, 17; histopathological effect of anoxia on central nervous system, 22; delimitation of subcortical tumors by direct electrography, 23; prefrontal lobotomy; survey of 331 cases, 23; penetrating head wounds, 121, histological changes in, in cases of fatal injury to head; alterations in nerve cells, 122; midline anomalies of; diagnosis by pneumoencephalography, 122; lipoma of corpus callosum; clinicopathological study, 123; meningioma of tuberculum sellae with bitemporal hemianopia, 123; neurosurgical service in evacuation hospital, 125; delayed post-traumatic abscess of, 233; nontraumatic hematomas, 233; mechanical results of development of tumor in craniovertebral cavity, 234; metastatic tumors of, 234; cerebral resections; 8 cases, 235; surgical problems in later stages of penetrating head injuries, 331; concussion and contusion, 332; cephalhematoma deformans, 333; craniotomy and total dissection as method in treatment of abscess of, 334; cerebral fungus following penetrating wounds, 447; analysis of abscesses of, observed during past 30 years, 447; malignancy of tumors of hypophysis; critique and case report, 447; complete extracapsular excision of tumors of hypophysis, 447; disturbances of ethmoid branches of ophthalmic nerve, with description of syndrome associated with chronic suppuration of olfactory fissure, 448; concerning phenomena of arrest of function by neural scars, 449; penetration of penicillin through normal and inflamed meninges, 451; method of encephalography, 548; behavior of hematological picture in commotio cerebri, 548; subdural pneumography, 605**
- Breast, Enlargement of, in pediatric practice, 27; prognosis of benign lesions of female, 28; experimental induction of mammary cancer, 29; histological classification of carcinoma of, 30; sarcoma of, 31; survival rates of radical mastectomy for unilateral and bilateral carcinoma of, 31; possibilities of roentgen therapy in treatment of cancer of, 90; bleeding nipple, 127; cancer of, and Paget's disease of, 127; diagnosis and treatment of carcinoma of female, 128; skeletogenous tumors of mammary gland, 239; late recurrences in skin following radical amputation of, for carcinoma, 240; resection of axillary vein in radical operation for cancer of mammary gland, 240; value of orchidectomy in treatment of carcinoma of male, 339; ultimate effects of suppression of ovarian hormone on development and evolution of mammary cancer, 452; comparative mor-**

- phological study of mammary glands with reference to known factors influencing development of mammary carcinoma in mice, 515; demodex folliculorum in human nipple, 555
- Breath presentation, Inquiry into causes of, 48r
- Brenner tumor, Contribution to case knowledge and histology of Brenner tumor, 259
- Bronchi, Roentgenology of draining, from tuberculous cavities, 197
- Bronchiectasis, Penicillin in treatment of, 34; lobectomy for, in children; 5 personal observations, 452; surgical treatment of, 555; cystic disease of lungs and its relationship to cavities due to, 555
- Brucellosis spondylitis, 278
- Burns, Electrolyte changes and chemotherapy in experimental, traumatic shock and hemorrhage, 95; acid, of eye, 115; symposium on, from Hartford circus disaster, 188; toxemia syndrome after; biochemical and pathological observations and studies, 188; superficial, of skin and eyes from scattered cathode rays, 200; Curling's ulcer in experimental; effect of penicillin therapy; correlation of observations with other recent evidence regarding pathogenesis of peptic ulcer, 250; acceleration of healing by pressure application to experimental thermal, 202, sequelae of; treatment by skin flaps, 202; histological and bacteriological study of healing, with inquiry into significance of local infection, 203; air hygiene in dressing rooms for, or major wounds, 397; mitosis and healing of corneal, 443; study of azotemia observed after severe, 511; amniotic membrane grafts in caustic, of eye; second degree, 542; management and surgical resurfacing of serious, 599; case of severe electric, with unusual sequence of complications, 600

CALCIFICATION OF LEFT AURICLE, 36

- Calcium, Early urolithiasis due to, 168
- Cancellous bone, Repair of cranial defects with reference to use of, 332
- Cancer, Of oral cavity; location and frequency, 21; experimental induction of mammary, 29; histological classification of carcinoma of breast, 30; survival rates of radical mastectomy for unilateral and bilateral carcinoma of breast, 31; diagnosis and management of uterine carcinoma and sarcoma, 52; social distribution of, of scrotum and of penis, 68; skeletal and pulmonary metastases from, of kidney, prostate, and bladder, 70, possibilities of roentgen therapy in treatment of, of breast, 90; electroendotherapy as adjuvant to radiotherapy in uterine, 91; growth of mammalian tumors in fertile eggs, is filtrable virus of, produced, 99; cutaneous carcinoma produced by coal tar of pilosebaceous origin, 100, of breast and Paget's disease of breast, 127; diagnosis and treatment of carcinoma of female breast, 128; problem of local recurrence after radical mastectomy for carcinoma, 128; multiple carcinomas of stomach, 145; histological study of effect of irradiation on adenocarcinoma of endometrium, 157, postmenopausal endometrium and its relation to adenocarcinoma of corpus uteri, 157; carcinoma subsequent to radiotherapeutic menopause, 158; roentgen treatment of malignant tumors of nasopharynx, 199; late recurrences in skin following radical amputation of breast for carcinoma, 240; resection of axillary vein in radical operation of, of mammary gland, 240; considerations about case with multiple gastric polyposis, hypertrophic gastritis and, of pyloric antrum, 250; surgical treatment of malignant tumors of duodenum exclusive of those arising from papilla of Vater, 252; carcinoid of ileocecal appendix, 254; of rectosigmoid and of sigmoid, 255; study of anorectal, 256; primary

- malignant tumors of spleen with reference to endothe liomas, 257; abdominopelvic sympathectomy for relief of pain of, of cervix, 263; bilateral primary sarcoma of kidney; report of case and review of literature, 270, carcinoma of larynx after roentgen irradiation, 305; betel chewing among natives of southwest Pacific islands; lack of carcinogenic action, 309; histological changes in central vegetative centers of hypothalamus in carcinoma as indication of vegetative functional disturbances, 309; transitional cell carcinoma, 328; of larynx; 5 year results of concentration radiotherapy, 330; value of orchidectomy in treatment of carcinoma of male breast, 339; bronchogenic carcinoma, 343; intrapericardial approach to lung root in treatment of bronchial carcinoma by dissection pneumonectomy, 344; submucosal lipomas of stomach; review of literature and report of case associated with carcinoma, 354; carcinoma of colon and rectum, 358; basis for sympathectomy for, of cervix uteri, 366; carcinoma of cervix in relation to age, with reference to young women, 366; lesions of penis, 378; lymphosarcoma of testicle, 379; treatment of malignant tumors by bacterial toxins as developed by late William B. Coley, reviewed in light of modern research, 414; colonic and proctoscopic diseases; collective review, 417; radium treatment of carcinoma of lip, 444; ultimate effects of suppression of ovarian hormone on development and evolution of mammary, 452; of lungs, 453; carcinoma of lower esophagus and cardia, 455; of rectum; preoperative preparation, postoperative complications and colostomy management, 466; selection of operation and technique of abdominopelvic resection for carcinomas of rectum, 466; abdominopelvic proctosigmoidectomy for, of rectum; conclusions based on 5 years' experience, 467; of Vater's papilla, 468; total pancreatotomy for carcinoma of pancreas in diabetic person; metabolic studies, 470; of cervical canal of uterus, 475; certain aspects of, of endometrium associated with pregnancy, 476; prostatic, treated by orchidectomy, 489; roentgenological diagnosis of, of stomach, 507; in childhood, 515; comparative morphological study of mammary glands with reference to known factors influencing development of mammary carcinoma in mice, 515; carcinogens and regeneration patterns after injury, 516; study of distribution of radioactive phosphorus in 3 cases of, 516; toxin therapy of experimental; influence of protozoan infections upon transplanted, 517; survey of oral carcinoma at Columbia-Presbyterian Medical Center, 546; benign attacks of goiter and severe heterogeneous type of; clinical and pathogenic considerations, 547; activities of department of esophageal diseases for year 1945 (service of R. Finocchietto), 556; diagnosis and treatment of carcinoma of esophagus, 557; bacteriology of peptic ulcer and gastric carcinoma, 561; modified Mikulicz operation for carcinoma of colon and its technique, 564; coincident removal of additional structures in resections for carcinoma of colon and rectum, 564; serological diagnosis of, of uterus, 570; vaginal and cervical cytology in diagnosis of, 570; of endometrium, 570; treatment of, of bladder for past 5 years; closed method of treatment, 579; treatment of, of penis, 580; liver changes and other effects of diethylstilbestrol during treatment of, of prostate gland, 581; development of squamous cell carcinomas in sinus tracts of chronic osteomyelitis, 592; occupational, 610; diagnosis of, 610
- Capsulorrhaphy, Experience with, for recurrent dislocation of shoulder, 497
- Carotid artery, Results following bands and ligatures on human internal, 180

- Cartilage, Peripheral inhibitory influence of large doses of testosterone on growth of epiphyseal, 310; dyschondroplasia, 382
- Cataract, Congenital, and other anomalies following rubella in mother during pregnancy; California survey, 117; corneal section with long bevel and conjunctival flap for extraction of; preliminary report, 323; associated with intraocular tumors, 443
- Catheter, Experimental production of pulmonary embolism by use of venous, 104
- Causalgia secondary to injury of major peripheral nerves, 233
- Cecum, Solitary diverticulitis of, 253; reflections on retrocecal appendix with regard to unusual complication, 254
- Cellophane, Treatment of syphilitic aneurysms by wrapping with, 555
- Cells, Cytological analysis of response of malignant tumors to irradiation as approach to biological basis for dosage in radiotherapy, 405; chemical factors and their role in inflammation, 407; tuberculosis or pseudotuberculosis of endometrium; clinical study and results of cytobornal explorations, 473; carcinogens and regeneration patterns after injury, 516
- Cellulitis, Anaerobic, due to actinomyces, associated with gas production, 608
- Cephalhematoma deformans, 333
- Cervical ribs, Bilateral, which became manifest after trauma of hands, 338
- Cervicitis, New method of treatment for vaginitis and, 371
- Cervix, Abdominopelvic sympathectomy for relief of pain of cancer of, 262; carcinoma of, in relation to age, with particular reference to young women, 366; tuberculosis of, 473; cancer of cervical canal of uterus, 475
- Cesarean section, Physick-Sellheim principle of extraperitoneal; elucidation of technique based on 175 cases, 58; continuous spinal and caudal analgesia in, 60; evaluation of treatment of persistently unengaged vertex in multipara, 371; for epilepsy in pregnancy, 371; disputed indications and techniques for, 482; delivery after, 482; continuous spinal analgesia in, 576
- Chemotherapy, Electrolyte changes and, in experimental burn, traumatic shock and hemorrhage, 95; streptomycin for tularemia, 190; suppurative labyrinthitis, 229; colonic and proctoscopic diseases; collective review, 417; investigation of role of, in wound management in Mediterranean theater, 502
- Chicago Lying-In Hospital, Review of maternal mortality at, from 1931 to 1945, 372
- Children, Osteomyelitis of jaws in infancy, 14; purulent meningitis of infancy and in, 12 months' survey of results of treatment with penicillin, 44; breast enlargement in pediatric practice, 27; acute hematogenous osteomyelitis in infancy, 71; flat feet in, 75; tuberculosis of stomach with reference to incidence in, 250; roentgenological skeletal changes in myeloma in, 303; cephalhematoma deformans, 333; supernumerary megacretum, 373; roentgen changes associated with pancreatic insufficiency in early life, 402; lobectomy for bronchiectasis in, 5 personal observations, 452; appendicitis in; review of 1,000 cases taken from records of Children's Hospital, Los Angeles, 462; cross infection in wards of, 513; cancer in childhood, 515; cranio-pharyngiomas in, 549; traumatic nerve lesions in, after supracondylar fracture of humerus, 592
- Chloroform, Spinal anesthesia and; comparison of mortality, 401
- Cholecystitis, Calculous perforating; biliointestinal fistula, 468; case of severe electric burns with unusual sequence of complications, 600
- Cholesterol, Effect of pituitary adrenotropic hormone on content of, and of ascorbic acid in adrenal glands in rat and guinea pig, 102
- Chordotomy, Surgery for relief of pain; anterolateral, 237; painful phantom limb treated by high cervical, 551
- Chorioepithelioma, Morphological study on proliferations, based on 10 cases, 61; extragenital, in male, 99; testicular, accompanied by excretion of prolan B and hypophyseal changes, 492
- Chylangioma of mesentery, Report of case and brief discussion of mesenteric cysts, 248
- Climacterium, D.B.E.; new synthetic estrogen, 54; D.B.E. in treatment of menopausal symptoms, 55
- Clostridia infections in war wounds on Karelian isthmus, 293
- Clostridium welchii, Puerperal infection treated with penicillin, 483
- Clotting agents, Topical use of, in surgery of prostate gland, 488
- Coagulation, Relation of certain fractions of plasma globulins to defect in, in hemophilia, 181
- Coal tar, Cutaneous carcinoma produced by, of pilosebaceous origin, 100
- Cocoon Grove disaster, Roentgenological findings in lungs of victims of, 88
- Cold, Tissue damage due to, 396; physiology of immobilization and local effects of heat and, 508
- Cold agglutinins, Blood transfusion to recipients with, 501
- Cold test, Studies on, as method for assay of adrenocortical steroids, 311
- Coley, William B., Treatment of malignant tumors by bacterial toxins as developed by late, reviewed in light of modern research, 414
- Colitis, Tuberculous ulcerative, or ulcerative, with superimposed tuberculous infection, 253
- Collective review, Summary of surgical aspects of certain sulfonamides and antibiotic agents, 1; treatment of ununited fractures of neck of femur, 105; splenectomy, with reference to its historical background, indications and rationale, and comparison of reported mortality, 209; treatment of hyperthyroidism with thiouracil; toxic reactions, 313; colonic and proctoscopic diseases, Part I, 417; colonic and proctoscopic diseases, Parts II and III, 521
- Colon, Periodic, spontaneously remittent volvulus and symptoms in cases of elongation of, 146; carcinoma of, and rectum, 358; closure of colostomies, 360; colonic and proctoscopic diseases; collective review, 417; colonic and proctoscopic diseases; collective review, 521; modified Mikulicz operation for carcinoma of, and its technique, 564; coincident removal of additional structures in resections for carcinoma of, and rectum, 564
- Colostomy, Closure of, 360; cancer of rectum; preoperative preparation, postoperative complications and management of, 466
- Commoio cerebri, Behavior of hematological picture in, 548
- Concussion, And contusion, 332; of spinal cord in war wounds, 336; behavior of hematological picture in commoio cerebri, 548
- Connective tissue, Sarcoma of spaces of, and of muscles of extremities, 100
- Convulsions, Ether; discussion and presentation of case, 85
- Cornea, Section of, with long bevel and conjunctival flap for cataract extraction; preliminary report, 323; mitosis and healing of burns of, 443
- Corpus luteum, Ovarian hemorrhages with attention to intra-abdominal hemorrhages from, 477
- Cranio-pharyngiomas in children, 549

- of mechanism of auditory apparatus, 324; correlations between bone and air conduction acuity measurements over wide frequency in different types of hearing impairment, 325; tympanosympathectomy; surgical technique for relief of tinnitus aurium, 325; otitis externa; clinical observations and microbiological flora, 326; secretory otitis media, 326; treatment of chronic otitis media, 326; apical petrositis; medical and surgical management in cases with and without complicating meningitis, 327; rare instance of fibromyoma of lobes of, 444
- Echinococcosis, Vertebral, 550
- Eclampsia, Histochemical age changes in normal and pathological placental villi (hydatidiform mole), 163
- Ectopia vesicae, 376
- Edema, Pulmonary, in chest wounds, 241
- Ehlers-Danlos syndrome, 409; description of 3 cases, 97
- Elbow, Sideswipe fractures, 386
- Electricity, Effects of injuries caused by, with reference to nervous system, 511; piezoelectric crystal measurements of pressure changes in abdomen of deeply anesthetized animals during passage of high velocity missile, 568
- Electroendothermy as adjuvant to radiotherapy in uterine cancer, 91
- Electrosurgery, Diathermocoagulation and roentgen therapy of malignant tumors of upper jaw, 445
- Electrotherapy, Delimitation of subcortical tumors by direct, 23
- Embolism, New findings with respect to nature, prevention and treatment of thrombosis and, 77; experimental production of pulmonary, by use of venous catheter, 104; thromboembolic disease, 181; pulmonary, 185; gas, in thoracic surgery, 245; challenge of thrombosis and, of blood vessels, and clinical use of anticoagulants, 286; bone-marrow, following fracture, 387; thrombosis; early diagnosis and abortive treatment with heparin, 598
- Empyema, Penicillin treatment of; report of 24 cases; review of literature, 243
- Encephalography, Method of, 548
- Endometriosis, Urogenital, 369; 250 cases of, 473; pathogenesis of ovarian, 570; pelvic, 573
- Endometrium, Tuberculosis or pseudotuberculosis of; clinical study and results of cytothoracal explorations, 473; certain aspects of cancer of, associated with pregnancy, 476
- Epididymitis, Pathogenesis of tuberculous, 167
- Epilepsy, Surgical treatment of vascular anomalies of pre-motor area producing, 333; cesarean section for, in pregnancy, 371
- Epiphysis, Treatment of slipped upper femoral, 283; peripheral inhibitory influence of large doses of testosterone on epiphyseal cartilaginous growth, 310; deformities following surgical epiphyseal arrest, 388
- Epithelioma, Primary, of trachea, 32
- Epithelization, Secondary, of cavities of chronic lung abscesses, 341
- Erosion, Late, of shell fragment into bladder, 488
- Ertrion, Toxic manifestations associated with ingestion of, 97
- Erysipeloid of Rosenbach; response to penicillin, 190
- Erythroblastosis fetalis in firstborn, 287
- Esophagus, Peptic ulcer of, 37; scleroderma with symptoms in, 37; varices of, 136; achalasia of, following depressed fracture of base of skull, 233; corrosive injuries of; treatment of acute corrosive esophagitis, 346; dysphagia due to causes other than malignant disease, 347; symposium; nonmalignant conditions of, 349; carcinoma of lower, and cardia, 455; activities of Department of Esophageal Diseases for year 1945 (from service of R. Finocchietto), 556; diagnosis and treatment of carcinoma of, 557
- Estrogens, D.B.E.; new synthetic, 54; influence of, on crystal structure of bone as revealed by x-ray diffraction studies on femora of mice, 416
- Ether, Convulsions due to; discussion and presentation of case, 85; endotracheal, and air for intrathoracic surgery, 87
- Ethylmorsuprenalin, Frontiers of anesthesia, 295
- Exophthalmos, Experimental production of, in fundulus by means of anterior pituitary extracts, 207; decompression of orbit, 441
- Eye, Injuries to, in war casualties aboard hospital ship, 15; oculomotor paralysis with partial recovery; report of case, 15; psychological reactions in soldiers to loss of vision of one, 16; dacryocystorhinostomy, 114; removal of magnetic foreign bodies, 114; return of vision in transplanted, of adult salamander after 7 days of refrigeration, 114; acid burns of, 115; basket type implant for use after enucleation, 115; uveal blastomycosis, 115; intraocular use of penicillin, 116; penicillin and vitamin C in treatment of hypopyon ulcer, 116; congenital cataract and other anomalies following rubella in mother during pregnancy; California survey, 117; meningioma of tuberculum sellae with bitemporal hemianopia, 123; superficial burns of skin and, from scattered cathode rays, 209; experimental production of exophthalmos in fundulus by means of anterior pituitary extracts, 207; epidemic keratoconjunctivitis associated with skin lesions, 226; ocular cysticercus cellulosa; report of case of parasite in vitreous, 226; operation for posterior route extraction of intraocular foreign bodies, 226; penicillin treatment of ocular inflammation, 226; penicillin in ophthalmology; bacteriological, experimental and clinical evidence of its value; 125 cases, 227; diathermy in glaucoma, 228; corneal section with long bevel and conjunctival flap for cataract extraction; preliminary report, 323; surgical treatment of strabismus, 323; Vogt-Koyanagi syndrome, 324; decompression of orbit, 441; paralysis of ocular elevation with and without ptosis, 442; paralysis of convergence with bilateral ring scotoma following injury to occipital region, 442; mitosis and healing of corneal burns, 443; keratoconjunctivitis sicca and buccoglossopharyngitis sicca with enlargement of parotid glands; report of 2 cases of Sjögren's syndrome, with pathological study of lacrimal gland and parotid glands in 1 case, 443; cataract associated with intraocular tumors, 443; syndrome of uveitis, 443; syphilitic uveitis; diagnosis, Herxheimer reaction and results of various treatments, including penicillin therapy, 444; amniotic membrane grafts in caustic burns of, (burns of second degree), 542; nutritional aspects of ophthalmology, 543; exophthalmic ophthalmoplegia, 543; oculoendocrine tularemia, 544; local treatment of intrabulbar infections; treatment of staphylococcal panophthalmitis by intrabulbar injection of penicillin, 544; transplantation of human vitreous, 544; hereditary degenerative diseases of retina; attempt at classification, 544; suprasellar meningiomas associated with scotomatous field defects, 549
- Eyelid, Repair and reconstruction of, 442
- FACE, Injuries of, and neck in war casualties, 20; arteriovenous aneurysms of scalp and, 113; control of bone fragments in maxillofacial surgery, 118; early management of injuries of, 185; treatment of casualties of jaw and, in British Army, 225; anesthesia of recent injuries of jaw and, 504

- Femur, Treatment of ununited fractures of neck of; collective review, 105; treatment of fractures of neck of, by Brazilian method of Godoy Moreira; extra-articular nailing, 173; treatment of slipped upper femoral epiphysis, 283; evolution of tuberculous osteitis of neck of, 383; anatomic study of round ligament of, 585**
- Fenestration, Surgical treatment of otosclerosis; improved technique of, 545**
- Fertility, Value of physiological substrates in sperm migration in selected cases of human, 55**
- Fetus, Inquiry into causes of breech presentation, 481**
- Fibrinolysis, Occurrence of, in shock; prothrombin time and plasma fibrinogen during hemorrhagic shock, 94**
- Fibroma of left rectus abdominis muscle in male, 559**
- Fibromyoma, Rare instance of, of ear lobes, 444; clinical observations on, of uterus, 474**
- Fibrosis, Etiology of acquired, of bladder neck, 166**
- Fibula, Isolated traumatic luxation of, 592**
- Fingers, Bacteriology of septic, 83; suture of fingernail in crushing injuries, 83; treatment of Dupuytren's contracture, 171; position of, and function deficiency in ulnar paralysis, 337**
- Fistula, Histological observations on healing of labyrinthine, in monkeys, 117; external fecal, 151; of penile urethra, 166; calculus perforating cholecystitis; bilio-intestinal, 468; traumatic arteriovenous, involving abdominal aorta and inferior vena cava, 500; preservation of vein in operations for arteriovenous, 594**
- Fixanol C, Treatment of hospital blankets with oil emulsions and bactericidal action of, (cetyl pyridinium bromide), 398**
- Fixation, Control of bone fragments in maxillofacial surgery, 118; delayed internal, of compound battle fractures in Mediterranean theater of operations, 176; bony union of intramedullary, 495**
- Folliculoma, Rare case of, of testicle, 401**
- Foot, Flat, in children, 74; protection of, immersed in cold water, 97; results of stabilizing operations on bones in paralytic, with or without transplantations of tendons, 173; penicillin in treatment of Madura; report of 2 cases, 205; indications for Syme amputation, 385; technique of Syme amputation, 590**
- Foramen, Hernia through, of Winslow, 568; hernia through, of Winslow emerging through gastrohepatic omentum, 569**
- Forceps for delivery, use and abuse, 265**
- Foreign bodies, Injection of oxygen into Tenon's capsule, 16; removal of magnetic, 114; operation for posterior route extraction of intracranial, 226; localization of, in chest, 300; surgical problems in later stages of penetrating head injuries, 331**
- Fowler's position, 364**
- Fractures, Study of 150 cases of upper jaw, in overseas maxillofacial center, 13; march (fatigue), of long bones of lower extremity and pelvis, 75; treatment of ununited, of neck of femur; collective review, 105; treatment of, of neck of femur by Brazilian method of Godoy Moreira, extra-articular nailing, 173; delayed internal fixation of compound battle, in Mediterranean theater of operations, 176; roentgenographic examination of ankle joint in malleolar, 107; treatment of jaw and face casualties in British Army, 223; achalasia of esophagus following depressed, of base of skull, 235; intramedullary pinning of diaphyseal, 270; of carpal scaphoid, 281; treatment of, of hip; surgical technique, 282; march, of inferior pubic ramus, 285; sideswipe, 386; trimalleolar, of ankle joint; conservative method of treatment, 386; bone-marrow embolism following, 387; intramedullary nail technique for treating, of long bones according to method of Kucencher, and indications, 387; so-called retarded or occult; significance of parallel projection in roentgen diagnosis of, 476; treatment of, of carpal scaphoid; report of 64 cases, 498; significance of minor bone injuries, 507; traumatic nerve lesions in children after supracondylar, of humerus, 592**
- Frostbite, Role of sympathectomy in treatment of immersion foot and, 25; tissue damage due to cold, 396**
- Fungi, Effect of some antibiotics on pathogenic, 103; cerebral, following penetrating wounds, 447**
- GALL bladder, Hemorrhage from, 152; papilloma of, 363**
- Ganglion, Sympathetic block of stellate; application in orthopedic conditions, 593**
- Gangrene, Spontaneous, of scrotum (Fournier's gangrene), 167; discussion on toxemia of gas, 399; anaerobic infection and, of war wounds in casualties from Philippine Islands, 601**
- Gas, Anaerobic cellulitis due to actinomyces, associated with production of, 608**
- Gastrectomy, Investigations of postoperative shock; hemocoagulation, plasma protein, and blood electrolytes after, 45**
- Gastritis, Cytological diagnosis of, 249; considerations about case with multiple gastric polyposis, hypertrophic, and cancer of pyloric antrum, 250**
- Gastroenterostomy, Gastric retention after posterior, for duodenal ulcer; prevention and treatment, 149**
- Gastrointestinal tract, Nocturnal gastric secretion, 43; thoracic gastric cyst, 43; review of literature on roentgenology of, for year 1944, 301; appendicitis in children; review of 1,000 cases taken from records of Children's Hospital, Los Angeles, 464; chronic relapsing pancreatitis; study of 29 cases without disease of biliary tract or, 469; microincineration study of flat epithelial layer covering alimentary tract, 559**
- Gastroscope, Roentgenologic study and, of gastric disease, 248; correlation of gastroscope, roentgenological and pathological findings in disease of stomach; analysis of 245 proved cases, 500**
- Gelatin, Sponge of; new hemostatic substance; studies on absorbability, 195**
- Genital organs (female), Prolapse of urethra in female; considerations based on 3 observations, 158; immediate and terminal results of surgical treatment of genital prolapse, 159; dosage measurements in roentgen irradiation of female pelvis, 199; clinicopathological study of 100 female urethras, 260; genital infarcts after abortion, 264; basis for sympathectomy for cancer of cervix uteri, 366; carcinoma of cervix in relation to age, with reference to young women, 566; uterine endometriosis, 369; primary melanopithelioma of female urethra, 478; clinical and pathological study of posterior female urethra, 571**
- Genital organs (male), Extragenital chorioepithelioma in male, 99; fistula of penile urethra, 166; pathogenesis of tuberculous epididymitis, 167; spontaneous gangrene of scrotum (Fournier's gangrene), 167; vasoseminal vesiculography and its clinical application, 168; clinical anatomy of prostatic tumors, 272; tumor of testicle, 273; cancerous and precancerous lesions of penis, 378; lymphosarcoma of testicle, 379; topical use of clotting agents in surgery of prostate gland, 483; retropharyngeal prostatic tumor, 489; varicocele, 491; rare case of folliculoma of testicle, 491; testicular chorioepithelioma accompanied by excretion of prolan B and hypophyseal changes, 492; solid tumors of epididymis, 581; roentgen therapy for malignant teratoma of testis, 581**
- Genitourinary tract, War wounds of, 60**
- Geriatric surgery, Basic principles in, 611**

- Gilchrist's disease, Uveal blastomycosis, 115
 Gingivitis, of pregnancy; history, classification and etiology, 575
 Glaucoma, Diathermy in, 228
 Glioma of retina and of brain in collateral lines in same family; genetics of, 17
 Glycogen, Assay of adrenocortical material by means of test with, in adrenalectomized mouse, 519
 Goiter, Particular aspects of osseous growth and calcium metabolism in case of exophthalmic, in child of 6 years, 328; benign attacks of, and severe heterogenous type of cancer, 547
 Gonococcus, Streptomycin resistant cocci, 191
 Gonorrhea, Chilling penicillin, 189
 Grafts, Repair of soft tissue war wounds, 82; return of vision in enucleated adult salamander eyes after 7 days of refrigeration, 114; use of Haynes' maxillary splint in case of grafting of mandible, 114; basket type implant for use after enucleation, 115; control of bone fragments in maxillofacial surgery, 118; treatment of Dupuytren's contracture, 171; results of stabilizing operations on bones in paralytic feet, with or without transplantations of tendons, 173; treatment of jaw and face casualties in British Army, 225; cuts, in surgery; review of results obtained with comments on indications and technique; report of cases, 289; sequelae of burns; treatment by skin, 292; repair of cranial defects; use of cancellous bone, 332; principles in reparative plastic surgery, 395; plastic correction of superficial vascular and pigmented nevi, 395; repair of surface defects of upper extremity, 396; use of cancellous bone in repair of defects about jaws, 440; ovarian and uterine, in woman and variations in urinary pregnandiol, 478; total avulsion of scalp; review of problem with presentation of case of skin, in which thrombin plasma fixation was used, 541; amniotic membrane, in caustic burns of eye (burns of second degree), 542; some uses for free muscle, in urology, 583; treatment of chronic osteomyelitis by use of muscle transplant or iliac, 585; management and surgical resurfacing of serious burns, 599; new and successful closed operative procedure for pilonidal sinus; gluteus maximus mobilization; sliding muscle graft procedure, 609
 Granuloma, Xanthoma or lipoid, of temporal bone; Hand-Christian-Schuller syndrome, 117; nonspecific intestinal, 149; malignant, of mediastinum of neoplastic developmental form with infiltration of pulmonary parenchyma, 557
 Granulosa cell tumor, Of ovary, 367; pathology and clinical course of, 477
 Gynecology, High peritonization in surgery, 574
- H**AND, Treatment of Dupuytren's contracture, 171; bilateral cervical ribs which became manifest after trauma of, 338
 Haptoglobin during pregnancy, confinement, and postpartum period, 480
 Hartford circus disaster, Symposium on burns from, 188
 Haynes splint, Use of, in case of grafting of mandible, 114
 Head, Cranial arteritis; critical evaluation of syndrome of "temporal arteritis" with report of case, 77; arteriovenous aneurysms of scalp and face, 113; penetrating wounds of, 121; histological changes in brain in cases of fatal injury to; alterations in nerve cells, 122; surgical problems in later stages of penetrating injuries of, 337; concussion and confusion, 332; paralysis of convergence with bilateral ring scotoma following injury to occipital region, 442; management of late injuries of, 548
- Healing, Acceleration of, by pressure application to experimental thermal burns, 292; experimental study on, of wounds; heart extract powder (Doljanski), 311
 Hearing, War injuries to auditory apparatus, 17; theory of mechanism of auditory apparatus, 324; correlations between bone and air conduction acuity measurements over wide frequency in different types of impairment of, 325; secretory otitis media, 326
 Heart, Calcification of left auricle, 36; clinical picture and therapy of injuries of, 133; surgery of patent ductus arteriosus, 133; constrictive pericarditis, 135; cardiovascular radiomorphology; usefulness and future, 197; treatment of acute arrhythmias during anesthesia by intravenous procaine, 296; neuronal damage from temporary cardiac arrest, 603
 Heart extract powder, Experimental study of healing of wounds; action of, (Doljanski), 311
 Heat, Physiology of immobilization and local effects of, and cold, 508
 Heat stroke, Postoperative, 502
 Hemagglutination, Irregular, after transfusion, 79
 Hemangioma, Of kidney, 270; treatment of, 305; vascular tumors of spinal cord associated with skin, 550
 Hematoma, Nontraumatic, 233; aerohematoma of sinuses, 327; displacement of kidney consequent upon spontaneous perineal, 485
 Hemoglobin, Some newer concepts of natural derivatives of, 393
 Hemophilia, Relation of certain fractions of plasma globulins to coagulation defect in, 181
 Hemorrhage, Extradural spinal, 24; selective treatment of antepartum, 57; report of case of acute hemorrhagic adrenitis, 63; occurrence of fibrinolysis in shock, prothrombin time and plasma fibrinogen during hemorrhagic shock, 94; electrolyte changes and chemotherapy in experimental burn, traumatic shock and, 95; from gall bladder, 152, of suprarenal glands in newborn, 161; synthetic production of vitamin K and its use in, and treatment of wounds, 187; prothrombinemia in hemorrhagic diatheses and its response to vitamin K, 206; treatment of internal, and hemorrhagic diatheses with vitamin K, 206; functional uterine, and treatment with testosterone, 260; tendency to, in thyrotoxicosis, 328; ovarian, with attention to intra-abdominal, from corpus luteum, 477; late secondary tonsillar; studies of ascorbic acid, 547; neurofibroma of small intestine with massive, 563
 Hemostasis, Gelatin sponge, new hemostatic substance; absorbability, 195
 Heparin, Mesenteric venous thrombosis; recovery after resection with, 352; thrombosis; early diagnosis and abortive treatment with, 598; anticoagulant therapy in thrombosis, 598
 Hepatitis, Transmission of infectious, by blood transfusion; 2 cases, 80
 Heredodegenerative disease of retina; attempt at classification, 544
 Hernia, Inguinal, and its repair, 42; postappendectomy interstitial inguinal, 42; lumbar herniations of intervertebral discs; value of surgical removal for naval personnel, 123; of lung, 339; use of rectus sheath and superior pubic ligament in direct and recurrent inguinal, 352; hiatus, of stomach as source of gastrointestinal bleeding, 353; modification of technique for cure of umbilical, in adults, 458; through foramen of Winslow, 568; through foramen of Winslow emerging through gastrohepatic omentum, 569
 Herniorrhaphy, Inguinal, from intra-abdominal perspective; retention of sac and intact external ring and means for proving adequacy of repair, 457

- Herpes zoster**, Site of facial nerve lesion in Ramsay Hunt's syndrome, 333
- Heraheimer reaction**, Syphilitic uveitis; diagnosis and results of various treatments, including penicillin therapy and, 444
- Hip**, Treatment of fractures of; surgical technique, 282; muscle-flap transplant for relief of painful monarticular arthritis (aseptic necrosis) of, 384; pathomechanics of, after shell operation, 184; roentgenological appearance, early and late, of congenital luxation of, treated with abduction splints, 584; exarticulation of lower extremities for malignant tumors, 588
- Histamine**, Action of curare and tubocurarine similar to that of, when injected intracutaneously and intrarterially in man, 505
- Hodgkin's disease**, Ovarian involvement in, 367; and pregnancy, 371
- Hookworm disease**, Study of small intestine, 83
- Hormones**, Influence of urinary cortinlike material on sodium and potassium metabolism, 370; ultimate effects of suppression of ovarian, on development and evolution of mammary cancer, 452; 259 cases of endometriosis, 473
- Hospital**, Blankets in, as source of infection, 398; treatment of blankets in, with oil emulsions and bactericidal action of "fixanol C" (cetyl pyridinium bromide), 398
- Humerus**, Traumatic nerve lesions in children after supracondylar fracture of, 592
- Hydatid disease**, Progress in knowledge of, 98
- Hydatidiform mole**, Histochemical age changes in normal and pathological placental villi (eclampsia), 103
- Hydrarthrosis**, Roentgenographic appearance of temporomandibular, 207
- Hydronephrosis**, Rupture of kidney tumors and, 375
- Hypernephroma**, Sedimentation rate in, 485; early metastases of, in third metacarpal bone of pulsating character, 485
- Hyperplasia**, Persistence and, of primary vitreous (tunica vasculosa lentis or retrolental fibroplasia), 16; unilateral, of mandibular condyle, 542
- Hypertension**, Small adenomas of adrenal cortex in, and diabetes, 63; malignant; neurosurgery of kidney, 64; surgery for, 125; present status of unilateral renal, 268; treatment of shock with serum from patients with, 202; sympathectomy for, 337
- Hyperthyroidism**, Ovarian struma with, 54; acute hyperthyroid crises; physiopathological study, 230; treatment of, with thioracil, with reference to toxic reactions; collective review, 313; radioactive iodine in thyroid physiology, 445, radioactive iodine in, 445
- Hypertrophy**, Pyloric stenosis with, 560
- Hypoglycemia**, Experiences in subtotal resection of pancreas in, 470
- Hypophysis**, Malignancy of tumors of; critique and case report, 447; complete extracapsular excision of tumors of, 447
- Hypotension and spinal anesthesia**, veritol test, 206
- Hypothalamus**, Histological changes in central vegetative centers of, in carcinoma as indication of vegetative functional disturbances, 309
- ICTERUS**, Splenectomy, historical background, indications, and rationale and comparison of reported mortality; collective review, 200
- Helitis**, Nonspecific intestinal granuloma, 149
- Ilium**, Subacute volvulus of terminal, 462
- Ilex**, Neurogenic, 561
- Ilium**, Treatment of chronic osteomyelitis by use of muscle transplant or iliac graft, 585
- Immersion foot**, Role of sympathectomy in treatment of, and frostbite, 25; protection against cold water, 57
- Immobiliation**, Physiology of, and local effects of heat and cold, 508
- Immunotransfusions**, Therapy of infected wounds and acute infections with, 203
- Incision**, Musculoplastic, for posterior thoracoplasty, 557
- Incontinence**, Evaluation of methods for treatment of urinary, 368; rapid and easily performed method of operation in urinary, 571
- Industry**, Physical capacity for work; principles of physiology with regard to; related to evaluation of working capacity of physically impaired, 205
- Infections**, Surgical aspects of certain sulfonamides and antibiotic agents; collective review, 1; labyrinthitis, 17; clinical use of penicillin in, of ears, nose and throat, 18; petrositis, 18; experimental gonococcal urethritis in human volunteers, 68; streptomycin for certain systemic, and its effect on urinary and fecal flora, 98; true infective bacterial pyuria, 163; penetration of penicillin into foci of, 180; penicillin therapy of, in 220 patients, 189; erysipeloid of Rosenbach; response to penicillin, 190; typhoid-bacillus, of surgical wound; treatment with urethane-sulfanilamide mixture, 191; penicillin in ophthalmology; bacteriological, experimental and clinical evidence of its value, including personal series of 125 cases, 227; tuberculous ulcer of tongue, 230; tuberculous ulcerative colitis or ulcerative colitis with superimposed tuberculous, 253; puerperal, 265; study of tuberculous strictures of ureter and their complications, 271; penicillin treatment of urinary, caused by pyogenic cocci, 276; treatment of bacillus proteus, with NU-455, 276; clostridia, in war wounds on Karelian isthmus, 293; histological and bacteriological study of healing burns with inquiry into significance of local, 293; therapy of infected wounds and acute, with immunotransfusions, 293; penicillin therapy; observations of 400 cases, 293; blastomycosis; review of literature and report of case involving meningitis, 309; deep, of neck with reference to role of dental foci, 328; Hodgkin's disease and pregnancy, 371; streptomycin in treatment of persistent urinary, 381; hospital blankets as source of, 398; air hygiene in dressing rooms for burns or major wounds, 397; discussion on toxemia of gas gangrene, 399; colonic and proctoscopic diseases; collective review, 417; vaginal flora during gestation, 480; clostridium welchii puerperal, treated with penicillin, 483; congenital abnormalities in infants following infectious diseases during pregnancy, with reference to rubella; third series of cases, 483; amebiasis of urinary tract, 492; cross, in children's wards, 513; amebiasis of skin and subcutaneous tissue; 3 cases with amebic ulceration of abdominal and thoracic wall following intestinal, 514; toxin therapy of experimental cancer; influence of protozoan, upon transplanted cancer, 517; pathogenicity of penicillin insensitive, 519; local treatment of intrabulbar; treatment of staphylococcal panophthalmitis by intrabulbar injection of penicillin, 544; anaerobic, and gangrene of war wounds in casualties from Philippine Islands, 601; anaerobic cellulitis due to actinomycetes, with gas production, 603
- Inflammation**, Penicillin treatment of ocular, 226; chemical factors and their role in, 407
- Injuries**, Eye, in war casualties aboard hospital ship, 151; war, to auditory apparatus, 17; war, of urinary tract, 63; suture of finger nail in crushing, 83; effect of blast on human ear, 117; histological changes in brain in cases of fatal, to head; alterations in nerve cells, 121; neurosurgical service in evacuation hospital, 123; clau-

- ical picture and therapy of heart, 133; pathogenesis clinical picture and therapy of, of chest, 138; last "hate", 155; early amyloid nephrosis following compound bone, 164; vascular, of extremities in battle casualties, 179; early management of facial, 185; causalgia secondary to, of major peripheral nerves, 233; newer concepts in treatment of paralyzed patient due to wartime, of spine; neurosurgical complications, 236; wartime laryngeal, 320; surgical problems in later stages of penetrating, of head, 331; corrosive, of esophagus; with reference to treatment of acute corrosive esophagitis, 346; battle, of arteries in World War II, 390; paralysis of convergence with bilateral ring scotoma following, to occipital region, 442; use of *curare* in oil in treatment of spasticity following, of spinal cord, 448; early nerve surgery in peripheral nerve, 450; orthopedic and rehabilitation service of Royal Air Force, 498; anesthesia of recent, of jaw and face, 504; significance of minor bone, 507; effects of electrical, with reference to nervous system, 512; carcinogens and regeneration patterns after, 516; management of late head, 548; to pancreas and their surgical treatment, 565; crush syndrome, 608
- Insufflation**, Therapeutic with uterine, in sterility, 55
- Insulin**, Treatment of diabetes mellitus without, 567
- Intervertebral discs**, Diagnosis of lumbar protrusions of, 123; lumbar herniations of; value of surgical removal for naval personnel, 123; roentgenographic signs of herniation of cervical, 293; lumbar herniations of; value of surgical removal for naval personnel, 335; late results of operative treatment for prolapses of, in lumbar region, 336; ruptured, 449
- Intestines**, Acute obstruction of small, 48; hookworm disease; study of small, 88; gastroduodenal invagination due to submucous lipoma of stomach, 142; early diagnosis and management of obstruction of small, 146; periodic, spontaneously remittent volvulus and symptoms in cases of colon elongatum, 146; mechanical intestinal obstruction following war wounds of abdomen, 147; some cases of tuberculosis of, in phthisics, with reference to prognosis, 148; nonspecific intestinal granuloma, 149; Meckel's diverticulum, 150; external fecal fistulas, 151; solitary diverticulitis of cecum, 253; tuberculous ulcerative colitis or ulcerative colitis with superimposed tuberculous infection, 253; acute volvulus of appendix, 254; carcinoma of ileocecal appendix, 254; reflections on retrocecal appendix with regard to unusual complication, 254; acute gastroduodenal obstruction (dilatation), 352; hiatus hernia of stomach as source of gastrointestinal bleeding, 353; treatment of perforated gastric and duodenal ulcer, 353; congenital duodenal obstruction; report of 6 cases and review of literature, 355; obstruction of, following abdominal battle wounds, 355; complete duodenal obstruction in newborn, 356; enterogenous cyst of ileocecal region, 356; ureteral implantation in, according to Coffey, 373; factors in diminution of mortality rate in acute obstructions of, 461; subacute volvulus of terminal ileum, 462; prolapse of rectum in adults, 464; restoration of continuity after resection of rectum, 464; calculeous perforating cholecystitis; biliointestinal fistula, 468; neurogenic ileus, 562; surgical treatment of tuberculosis of, 563; neurofibroma of small, with massive hemorrhage, 563; transplantation of duplicated ureters into; 3 cases, 579
- Intoxication**, With vitamin D, 410
- Intumescence**, Four cases of diaphragmatic, 258
- Invagination of stomach**, 249
- Iodine**, Radioactive, in thyroid physiology, 445; radioactive, in hyperthyroidism, 445
- Irradiation**, Histological study of effect of, on adenocarcinoma of endometrium, 157; superficial burns of skin and eyes from scattered cathode rays, 200; newer investigations of radiation effects and their clinical applications; Pancoast lecture, 202; cytological analysis of response of malignant tumors to, as approach to biological basis for dosage in radiotherapy, 405; radioactive iodine in thyroid physiology, 445; radioactive iodine in hyperthyroidism, 445; distribution of radioactive phosphorus in 3 cases of cancer, 516; treatment of Cushing's syndrome, 549
- Ischemia**, Sympathectomy for, following femoral artery ligation, 25
- JAUNDICE**, Bilirubin production of human organism and its significance in pathogenesis of, 48; homologous serum, following administration of commercial pooled plasma, 183
- Jaw**, Study of 150 cases of fracture of upper, in overseas maxillofacial center, 13; osteomyelitis of, in infancy, 14; osteomyelitis of: therapeutic suggestions, 14; surgical treatment of mandibular prognathism, 19; control of bone fragments in maxillofacial surgery, 118; treatment of, and face casualties in British Army, 225; deep infection of neck with reference to role of dental foci, 328; transitional cell carcinoma, 328; study of internal derangement of temporomandibular joint, 440; use of cancellous bone in repair of defects about, 440; diathermocoagulation and roentgen therapy of malignant tumors of upper, 445; anesthesia of recent injuries of, and face, 504
- Joints**, Osteoarthritis alkaptonuria (ochronosis), with description of case, 72; early results of treatment of gunshot wounds of limb joints aided by penicillin therapy, 74; Ehlers-Danlos syndrome; 3 cases, 97; ankylosis of temporomandibular, 113; rupture in aponeurosis of shoulder; its treatment, 172; roentgenographic examination of ankle, in malleolar fractures, 197, Bechterew's disease from roentgenological point of view, 198, recurrent dislocations of shoulder, 281; reflex hyperemic dislocations regional to, of extremities, 303; osteoarthritic tuberculosis and trauma, 382; pathomechanics of hip after shelf operation, 384; muscle flap transplant for relief of painful monarticular arthritis (aseptic necrosis) of hip, 384; sideswipe fractures, 386, malleolar fractures of ankle; conservative method of treatment, 386; Ehlers-Danlos syndrome, 409; condylar movement in study of internal derangement of temporomandibular, 440; physiology of immobilization and local effects of heat and cold, 508, osteochondritis dissecans and torn lateral meniscus, 505; sympathetic block of stellate ganglion; application in orthopedic conditions, 593
- KELOIDS** and their treatment, 90
- Keratoconjunctivitis**, Epidemic, with skin lesions, 226; dry, and buccoglossopharyngitis sicca with enlargement of parotid glands; 2 cases of Sjögren's syndrome, with pathological study of lacrimal gland and parotid glands in 1 case, 443
- Kidney**, Malignant hypertension; neurosurgery of, 64; skeletal and pulmonary metastases from cancer of prostate, bladder and, 70; early amyloid nephrosis following compound bone injuries, 164; tumors of renal pelvis, 164; angioma of, 165; pathogenesis of tuberculous epididymitis, 167; present status of unilateral renal hypertension, 268; nephroptosis with co-existing lesions, 269; bilateral primary sarcoma of; report of case and review of literature, 270; hemangioma of, 270; subcutaneous liver ruptures and hepato-

- orenal syndrome, 362; study of Wilms' tumor, 368; sclerosing injection of polycystic, following surgical exposure, 373; rupture of tumors of, and hydronephroses, 375; alterations in normal and decapsulated, caused by transfusion of heterogenous blood, 394; sedimentation rate in hypernephroma, 485; displacement of, consequent upon spontaneous perirenal hematoma, 485; true aneurysms of renal artery, 486; papilloma of ectopic, 487; tumors of renal pelvis, 487; ureteroceles, 488; tuberculosis of renal pyramids, 578; prognosis and problems in renal tumors, 578
- Klippel-Feil syndrome, Analysis of, 608
- Knee, Arthrosis in, after meniscectomy, 493
- L**ABOR, Control of pain and fear in management of, and delivery, 57; Physick-Sellheim principle of extraperitoneal cesarean section; elucidation of technique based on 175 cases, 58, continuous spinal and caudal analgesia in cesarean section, 60, experience with Bracht's maneuver in delivery in cases of pelvic presentation, 264; premature delivery, causes and results, 264; forceps for delivery; use and abuse, 265; cesarean section for epilepsy in pregnancy, 371; evaluation of treatment of persistently unengaged vertex in multipara, 371; disputed indications and techniques for cesarean section, 482; delivery after cesarean section, 482; induction of, with methergine, 576
- Labyrinth, Histological observations on healing of fistulas in, 117, hydrops of; (Ménière's disease); diagnosis and results of surgery of, 229
- Labyrinthitis, One case, 17, suppurative, 229
- Laparotomy, Pathogenesis of postsalpingectomy endometriosis in scars after, 56
- Larynx, Carcinoma of, after roentgen irradiation, 305; wartime laryngeal injuries, 329; cancer of; 5 year results of concentration radiotherapy, 330
- Leg, Vascular injuries of extremities in battle casualties, 179; refrigeration in orthopedic and traumatological surgery, 499; retracted and short amputation stump of, treatment and prosthesis, 539
- Leniè's syndrome, Case of obliteration of bifurcation of aorta treated by resection of bifurcation, 595
- Leucemia, Primary endothelioma of pleura; patient with chronic lymphatic, 36, effects of radioactive sodium and of roentgen rays on normal and leucemic mice, 89; results of roentgen treatment of, 395; prolongation of life with prevention of, by thymectomy, 415
- Leucosarcoma, 611
- Leucotoxin, Chemical factors and their role in inflammation, 407
- Ligament, Use of rectus sheath and superior pubic, in direct and recurrent inguinal hernia, 352, anatomic study of round, of femur, 585
- Ligatures, Results following bands and, on human internal carotid artery, 180
- Lipoma, Of corpus callosum; clinicopathological study, 123; gastroduodenal invagination due to submucosa, of stomach, 142, of bronchus; benign neoplasms and case of endobronchial, 342, submucosal, of stomach, case associated with carcinoma, 354
- Lithiasis, Incidence of 665 personal cases of urinary, 583
- Liver, Transmission of infectious hepatitis by blood transfusion, 2 cases, 80; aneurysm of hepatic artery, 152; changes in, in surgical conditions, 152, pancreatitis; anatomic study of pancreatic and extrahepatic biliary systems, 152; synthetic adhesives in treatment of wounds of, and other surgical conditions; preliminary report, 195; pyogenic abscess of, 250; hereditary non hemolytic bilirubinemia, 361; subcutaneous ruptures of, and hepatorenal syndrome, 362; war wounds of, 362; changes in, and other effects of diethylstilbestrol during treatment of prostate gland cancer, 581
- Lobectomy, Technique of, with reference to individual ligation of parts of pedicle, 346, for bronchiectasis in children; 5 personal observations, 452, closure of bronchus in pneumonectomy and, 454
- Lobotomy, Prefrontal; survey of 331 cases, 23
- Lobstein's disease, Study of pathogenesis of idiopathic osteopetrosis, 382
- Lungs, "Wet," in war casualties, 51; penicillin in treatment of bronchiectasis, 34; putrid abscess of, 35; new treatment for postoperative pulmonary collapse, 81; postoperative pulmonary complications, 81; roentgenological findings in, of victims of Coconut Grove disaster, 88; experimental production of pulmonary embolism by use of venous catheter, 104; cystic disease of, 130; pulmonary embolism, 185; roentgenology of draining bronchi from tuberculous cavities, 197; pulmonary edema in chest wounds, 241; attempt to treat pulmonary suppurations with endobronchial instillations of penicillin, 242; primary tumors of, 242, abscess of, 242; hernia of, 339; extrapleural pneumolysis in pulmonary tuberculosis, 340, secondary epithelialization of cavities of chronic abscesses of, 341; surgical treatment of abscess of middle lobe of right, 341; lipoma of bronchus; discussion of benign neoplasms and report of case of endobronchial lipoma, 342; bronchogenic carcinoma, 343; intrapericardial approach to root of, in treatment of bronchial carcinoma by dissection pneumonectomy, 344; roentgen and clinical problems in so called solitary metastatic tumors in chest, 345; technique of lobectomy with reference to individual ligation of parts of pedicle, 346; lobectomy for bronchiectasis in children; 5 personal observations, 452; abscess of; report of 46 operated cases, 452; cancer of, 453; surgical treatment of bronchiectasis, 453; cystic disease of, and its relationship to bronchiectatic cavities, 555; malignant granuloma of mediastinum of neoplastic developmental form with infiltration of pulmonary parenchyma, 557
- Lymph glands, Primary endothelioma of pleura; report of case in patient with chronic lymphatic leucemia, 36; motor disturbances following excision of, of neck; how may we avoid them, 330
- Lymphosarcoma of testicle, 379
- Lymph system, Histological effects of radiophosphorus on normal and lymphomatous mice, 89
- M**ALACIOLAKIA of bladder, 166
- Malaria, Surgery in, 99
- Malignancy, Case of hypertension; neurosurgery of kidney, 64; management of tumors of testis, 379; of tumors of hypophysis, critique and case report, 447; osteogenic osteoblastoma with myeloid, 494; granuloma of mediastinum of neoplastic developmental form with infiltration of pulmonary parenchyma, 557; myoma malignum; anatomopathological contribution, 610
- Mandible, Surgical treatment of prognathism involving, 19; ankylolysis of temporomandibular joint, 123; use of Haynes' maxillary splint in case of grafting of, 114; roentgenographic appearance of temporomandibular hydrarthrosis, 207; condylar movement in study of internal derangement of temporomandibular joint, 440; congenital deformities of, in newborn infants, 545; unilateral hyperplasia of condyle of, 542; anesthetic management during reconstructive surgery of, 542
- Marroa, Prothrombin level of peripheral blood and sternal, 392

- Mastectomy, Survival rates of radical, for unilateral and bilateral carcinoma of breast, 31; local recurrence after radical, for carcinoma, 128
- Mastoid, Radical operation on, 118; subacute osteitis of atlas following suppurative, of, or of lateral region of throat, 495
- Maxilla, Temporomaxillary actinomycosis caused by anaerobic actinomycetes of Wolf-Israel type cured by combination of sulfa drugs and roentgen therapy, 541
- Meckel's diverticulum, 150
- Mediastinum, Clinical and roentgenological aspects of differential diagnosis of tumors of, 137; surgery of, 137; tumors of, 349; teratoma of anterior, in group of military age; study of 16 cases and review of theories of genesis, 456; malignant granuloma of, of neoplastic developmental form with infiltration of pulmonary parenchyma, 557
- Medulla, Bony union of intramedullary fixation, 495
- Melanopithelioma, Primary, of female urethra, 478
- Ménière's disease, Hydrops of labyrinth; diagnosis and results of labyrinth surgery, 219
- Meninges, Blastomycosis; brief review of literature and report of case involving, 309; penetration of penicillin through normal and inflamed, 431
- Meningioma, Of tuberculum sellae with bitemporal hemianopia, 123; suprasellar, associated with scotomatous field defects, 549
- Meningitis, Purulent, of infancy and childhood; 12 months' survey of results of treatment with penicillin, 24; apical petrositis; medical and surgical management in cases with and without complicating, 327
- Meningococcus, Streptomycin resistant cocci, 191
- Menisectomy, Arthrosis in knee after, 495
- Menopause, Postmenopausal endometrium and its relation to adenocarcinoma of corpus uteri, 157; carcinoma subsequent to radiotherapeutic, 158
- Mesentery, Chylangioma of, with report of case and brief discussion of cysts involving, 248; venous thrombosis of; recovery after resection with heparin, 352
- Mesothelioma, Primary, (endothelioma) of pleura, 244
- Metabolism, Influence of urinary cortinlike material on sodium and potassium, 310; particular aspects of osseous growth and, of calcium in case of exophthalmic goiter in child of 6 years, 328; total pancreatectomy for carcinoma of pancreas in diabetic person; studies on, 470
- Metastases, Skeletal and pulmonary, from cancer of kidney, prostate, and bladder, 70; tumors of brain, 234; early, of hypernephroma in third metacarpal bone of pulsating character, 485
- Methergine, Induction of labor with, 576
- Methylcholanthrene, Action of, on certain scars of skin in mice, 412
- Meyer, Robert, Dysgerminoma ovarii, 368
- Microincineration study of flat epithelial layer covering the alimentary tract, 559
- Mikulicz operation, Discussion of modified, for carcinoma of colon and its technique, 564
- Miller-Abbott tube, Factors in diminution of mortality rate in acute intestinal obstructions, 461
- Mitosis and healing of corneal burns, 443
- Morbidity, Studies of surgical; effect of prostigmine on urinary tract in gynecological survey, 160
- Mortality, Review of maternal, at Chicago Lying-in hospital, 1931-1945, 372; spinal anesthesia and chloroform; comparison of, 401; factors in diminution of rate of, in acute intestinal obstructions, 461
- Mouth, Cancer of oral cavity; its location and frequency, 21; tumors of sublingual glands, 118; oral plasma feeding, 205; radium treatment of carcinoma of lip, 444; survey of oral carcinoma at Columbia-Presbyterian Medical Center, 546
- Muscles, Sarcoma of connective tissue spaces and of, of extremities, 100; rhabdomyosarcoma of skeletal, 278; spasmodic torticollis; severe organic type treated by combined operation, rhizotomy, and fusion, 383
- Mycophenolic acid, Antibiotic, from penicillium brevicompactum Dierckx, 102
- Myelography, Late results of operative treatment for intervertebral disc prolapses in lumbar region, 336
- Myeloma, Roentgenological skeletal changes in, in childhood, 303
- Myeloplax, Malignant osteogenic osteoblastoma with, 494
- Myoma, Treatment of uterine, 474; significance of, of uterus in pregnancy, 576; malignum; anatomopathological contribution, 610
- NAILING**, Treatment of fractures of neck of femur by Brazilian method of Godoy Moreira; extra-articular, 173; intramedullary technique of, for treating fractures of long bones according to method of Kuentscher, and indications, 387
- Nasopharynx, Roentgen treatment of malignant tumors of, 199
- Neck, Injuries of face and, in war casualties, 20; deep infection of, with particular reference to role of dental foci, 328; motor disturbances following excision of lymph glands of; how may we avoid them, 330; spasmodic torticollis; severe organic type treated by combined operation, rhizotomy and fusion, 383; analysis of Klippel-Feil syndrome, 608
- Nephroptosis, Frequency of, during years of war, 575
- Nephropathy with coexisting lesions, 269
- Nerves, Usefulness of low lumbar sympathectomies in surgery of obturator nerve as auxiliary method in treatment of spastic paraplegies in Pott's disease, 25; late reactions following suture of, with integral physiological restoration of nerve, 121; histological changes in brain in cases of fatal injury to head; alterations in cells of, 122; interruption of sympathetic nervous system in relation to trauma, 124; motor disturbances following excision of lymph glands of neck; how may we avoid them, 330; site of lesions of facial, in cases of Ramsay Hunt's syndrome, 333; position of fingers and function of deficiency in ulnar paralysis, 337; sympathectomy for hypertension, 337; distant results in treatment of chronic pancreatitis by unilateral splanchnicotomy, 363; disturbances of ethmoid branches of ophthalmic, with description of syndrome associated with chronic suppuration of olfactory fissure, 448; phenomena of arrest of function by neural scars, 449; experience with early surgery of, in injuries of peripheral, 450; treatment of acute pancreatitis by infiltration of splanchnic, 469; effect of sympathetic and vagus, on activity of human ureters, 487; brachial plexus paralysis from gunshot wounds, 551; painful nocturnal paresthesias of upper extremities, 552; peripheral nerve injuries; results of early suture of, 552; sympathectomy in peripheral vascular sclerosis, 553; traumatic lesions of, in children after supracondylar fracture of humerus, 592; neuronal damage from temporary cardiac arrest, 603
- Nervous system, Histopathological effect of anoxia on central, 22; lesions of aqueduct of Sylvius, 22; surgical treatment of vascular anomalies of premotor area producing epilepsy, 333; effects of electrical injuries with particular reference to, 511
- Neuritis, Perforated gastric ulcer in patient with gastric, 353

- Neurofibroma of small intestine with massive hemorrhage, 563
- Neurofibromatosis, Deformities of spine in multiple, (von Recklinghausen), 337
- Neuronitis, Gestational, 48r
- Nevus, Plastic correction of superficial vascular and pigmented, 395
- Newborn, Decrease of serum cholesterol ester in hemolytic disease of, 60; cord transfusions in, infants, 161; hemorrhage of suprarenal glands in, 161; oral plasma feeding, 205; rubella in pregnancy, 263; obstetrician's responsibility for hazards of first few days of life, with reference to anoxia and prematurity, 266; results in 18,600 booked deliveries, 266; erythroblastosis fetalis in firstborn, 287; complete duodenal obstruction in, 356; further observations upon imperforate anus, 359; inquiry into causes of Breech presentation, 48r; congenital abnormalities in infants following infectious diseases during pregnancy, with special reference to rubella; third series of cases, 483; some observations on penicillin, 504; congenital mandibular deformities in, 542; asphyxia of, 577
- Nipple, Bleeding, 127
- Nitrogen, Amino acids in production of plasma protein and balance of, 307
- Nitrous Oxide, Curare and, anesthesia for lengthy operations, 86
- Nose, Clinical use of penicillin in infections of ear, throat and, 18; tissue changes produced in nasal mucous membrane of normal mice by prolonged local administration of some solutions containing sulfonamide compounds, 18; colloidal nasal tamponades, 19; aerohematoma of sinuses, 327; nasopharynx; study of 140 autopsy specimens, 546
- NU-453, Treatment of bacillus proteus infections with, 276
- Nutrition, Induction of vitamin C subnutrition, 205; problem of, in postoperative care of abdominal wounds of warfare, 502; aspects of, in ophthalmology, 543
- Nylon, Nonadherent surgical dressings, 506
- O**BESITY, Pituitary lesions accompanying, 102
- Obstetrics, Blood, blood derivatives and blood substitutes in, and gynecologic practice, 54; penicillin in, 60; obstetrician's responsibility for hazards of first few days of life, with reference to anoxia and prematurity, 266; review of maternal mortality at Chicago Lying-in Hospital 1931-1935, 372
- Obstruction, Acute, of small intestine, 48, early diagnosis and management of, of small intestine, 146; mechanical intestinal, following war wounds of abdomen, 147; study of ureters in, of bladder neck, 165; acute gastroduodenal, (dilatation), 352; congenital duodenal; 6 cases and review of literature, 355; intestinal, following abdominal battle wounds, 355
- Occlusion, Lesions of aqueduct of Sylvius, 22; surgical management of arterial, 180
- Oil, Treatment of hospital blankets with emulsions of, and bactericidal action of "fixanol C" (cetyl pyridinium bromide), 398
- Omentum, Effernia through the foramen of Winslow emerging through gastrohepatic, 569
- Operation, Myometrectomy, 52; for sterility, 53; reflections on radical mastoid, 118; indications for Syme amputation, 385; rapid and easily performed method of, in urinary incontinence, 575; new and successful closed procedure for pilonidal sinus; gluteus maximus mobilization; sliding muscle graft procedure, 600
- Ophthalmic nerve, Disturbances of ethmoid branches of, with description of syndrome associated with chronic suppurative of olfactory fissure, 448
- Ophthalmology, Penicillin in; bacteriological, experimental and clinical evidence of its value, including personal series of 125 cases, 227; nutritional aspects of, 543
- Ophthalmoplegia, Oculomotor paralysis with partial recovery; report of case, 15; exophthalmic, 543
- Orbit, Decompression of, 447
- Orchidectomy, Value of, in treatment of carcinoma of male breast, 330; prostatic cancer treated by, 489
- Osteitis, Evolution of tuberculous, of femoral neck, 383; subacute, of atlas following suppurative of mastoid or of lateral region of throat, 495
- Osteoarthritis alkaptouria (ochronotic) with description of case, 72
- Osteoplastoma, Malignant osteogenic, with myeloplastes, 494
- Osteochondritis dissecans and torn lateral meniscus, 583
- Osteochondrosis, On incidence of, 171
- Osteomyelitis, Of jaws in infancy, 14; of jaws; therapeutic suggestions, 54; acute hematogenous, in infancy, 71; penicillin for, 278; treatment of acute, with penicillin, 493; penicillin in chronic, 493; of sphenoid bone, 541; acute hematogenous, treated with penicillin, 584; first results in treatment of, with penicillin, 583; treatment of chronic, by use of muscle transplant or iliac graft, 585; development of squamous cell carcinomas in sinus tracts of chronic, 592
- Osteosporosy, Contribution to study of pathogenesis of idiopathic, 382
- Osteotomy, Treatment of united fractures of neck of femur; collective review, 105
- Otitis externa, Clinical observations and microbiological flora, 326
- Otitis media, Masking effect of sulfonamide when used in treatment of acute, 229; secretory, 326; treatment of chronic, 326
- Otosclerosis, Surgical treatment of; preliminary report on improved fenestration technique, 545
- Ovary, Ovarian struma with hyperthyroidism, 54; neoplasms in apparently normal, 138; dermoid cysts of; clinical and pathological significance, 299; granulosa cell tumor of, 367; involvement of, in Hodgkin's disease, 367; Robert Meyer dysgerminoma ovarii, 368; uncomplicated prolapse of, as cause of acute abdominal pain, 476; investigation of tumors of, 477; hemorrhages of, with attention to intra-abdominal hemorrhages from corpus luteum, 477; pathology and clinical course of granulosa cell tumors, 477; uterine and ovarian grafts in woman and variations in urinary pregnandiol 478; pathogenesis of endometriosis of, 570; value of smears from vaginal secretion in differential diagnosis of ovarian activity in women, 572
- Ovulation, General survey of vaginal smear and use in research and diagnosis, 250
- Oxygen, Injection of, into Tenon's capsule, 16; effect of intravenous administration of, on shock in dogs and human beings, 82; use of, and of substances liberating, in treatment of anaerobic peritonitis in guinea pigs, 520
- P**AGET'S disease, Breast cancer and, of breast, 127
- Pain, Paroxysmal abdominal, 57; control of, and fear in management of labor and delivery, 57; surgery for relief of; anterolateral chordeotomy, 237; abdominopelvic sympathectomy for relief of, in cancer of cervix, 262
- Pancoast lecture, Newer investigations of radiation effects and their clinical applications, 202
- Pancreas, Communication between duodenum and, 148; roentgen changes associated with insufficiency of, in early life, 402, roentgen diagnosis of cyst of, 402; ex-

- periences in subtotal resection of, in hypoglycemia, 470; injuries to, and their surgical treatment, 565; adenoma of islets of Langerhans and pregnancy, 567
- Pancreatectomy**, Total, for carcinoma of pancreas in diabetic person; metabolic studies, 470
- Pancreatitis**, Anatomic study of pancreatic and extrahepatic biliary systems, 152; acute, and splanchic block, 153; distant results in treatment of chronic, by unilateral splanchicotomy, 363; chronic relapsing; study of 29 cases without disease of biliary or gastrointestinal tract, 469; treatment of acute, by infiltration of splanchic nerves, 469
- Panhematoma**, Primary congenital and secondary acquired splenic, 50
- Papilloma**, Of gall bladder, 363; of ectopic kidney, 487
- Paralysis**, Oculomotor, with partial recovery; report of case, 15; newer concepts in treatment of, due to war time injuries of spine; neurosurgical complications, 236; rehabilitation of patients totally paralyzed below waist, with reference to making them ambulatory and capable of earning living; control of urination, 237, acute anterior poliomyelitis complicating pregnancy, 263; position of fingers and function deficiency in ulnar, 337; of ocular elevation, with and without ptosis, 442; of convergence with bilateral ring scotoma following injury to occipital region, 442; gestational neuronitis, 487; brachial plexus, from gunshot wounds, 551
- Parasite**, Ocular cysticercus cellulosa; case of, in vitreous, 226; demodex folliculorum in human nipple, 555
- Parathyroids**, Parathyroidal tetany and pregnancy, 370
- Paresthesia**, Painful nocturnal, of upper extremities, 552
- Parotid glands**, Keratoconjunctivitis sicca and buccoglossopharyngitis sicca with enlargement of; 2 cases of Sjögren's syndrome, with pathologic study of lacrimal gland and, in 1 case, 443; adenodysplasia of, and submaxillary salivary glands, 546
- Paroxysmal abdominal pain**, 51
- Pelvis**, March (fatigue) fractures of long bones of lower extremity and, 75; tumors of renal, 164; dosimetry measurements in roentgen irradiation of female, 199; pelvic parietal phlegmon; special type of phlegmon of broad ligament, 261; tumors of renal, 487
- Penicillin**, Summary of surgical aspects of certain sulfonamides and antibiotic agents; collective review, 1; thrombophlebitis of lateral sinus; treatment with, 13; osteomyelitis of jaws; therapeutic suggestions, 14; in aqueous humor, 16; labyrinthitis; treatment with, 17; clinical use of, in infections of ears, nose and throat, 18; purulent meningitis of infancy and childhood; 12 months' survey of results of treatment with, 24; in treatment of bronchiectasis, 34; in obstetrics, 60; acute hematogenous osteomyelitis in infancy, 71; early results of treatment of gunshot wounds of limb joints aided by therapy with, 74; in tetanus, 84; and vitamin C in treatment of hypopyon ulcer, 116; intraocular use of, 116; acutely infected pleural effusions; techniques of treatment with, 131; fistula of penile urethra, 166, chilling, 189; penetration of, into foci of infection, 189; therapy of infections in 220 patients, 189; acquired resistance of staphylococci to action of, 199; erysipeloid of Rosenbach; response to, 190; treatment of ocular inflammation, 226; in ophthalmology; bacteriological, experimental, and clinical evidence of its value; 125 cases, 227; attempt to treat pulmonary suppurations with endobronchial instillations of, 242; treatment of empyema with, 24 cases; review of literature, 243; treatment of gunshot wounds of chest in field aided by therapy with, 245; Curling's ulcer in experimental burns; effect of therapy with; correlation of observations with other recent evidence regarding pathogenesis of peptic ulcer, 250; prenatal syphilis, 266; treatment of urinary infections caused by pyogenic cocci, 276; for osteomyelitis, 278; therapy with; clinical and laboratory observations of 400 cases, 294; in treatment of Madura foot; 2 cases, 295; effect of, on septicemia caused by anaerobic microbes, 401; reactions to, 412; syphilitic uveitis; diagnosis, Herxheimer reaction, and results of various treatments including therapy with, 444; analysis of brain abscesses observed during past 30 years, 447; penetration of, through normal and inflamed meninges, 451; clostridium welchii puerperal infection treated with, 483; treatment of acute osteomyelitis with, 403; in chronic osteomyelitis, 404; observations on, 504; delayed reaction of, 514; pathogenicity of infection insensitive to, 519; local treatment of intrabulbar infections; treatment of staphylococcal panophthalmia by intrabulbar injection of, 544; acute hematogenous osteomyelitis treated with, 584; first results in treatment of osteomyelitis with, 584
- Penicillium brevicompactum** Dierckx, Mycophenolic acid, an antibiotic from, 102
- Penis**, Social distribution of cancer of scrotum and cancer of, 68; cancerous and precancerous lesions of, 378; treatment of cancer of, 580
- Periarteritis nodosa**, Clinical manifestations and post-mortem findings with report of 6 cases, 595
- Pericarditis**, Constrictive, 135
- Peripheral nerves**, Causalgia secondary to injury of major, 233; experiences with early nerve surgery in injuries of, 450; injuries of, results of early nerve suture, 552
- Peritoneum**, Supposed difference in defensive power of, in distinct sectors of abdomen, 247, pseudomyxoma of, 248; multiple peritoneal autotransplantation of splenic tissue following traumatic rupture of spleen, 471; hernia through foramen of Winslow, 568
- Peritonitis**, Causes of acute, observed at autopsy table, 247; notes concerning encapsulating; 459; use of oxygen and oxygen liberating substances in treatment of anserole, in guinea pigs, 520
- Peritonization**, High, in gynecological surgery, 574
- Pes planus**, Diagnosis of, with x-rays, 72
- Petrositis**, 18, apical; medical and surgical management in cases with and without complicating meningitis, 327
- Phantom limb**, Painful, treated by high cervical chordotomy, 551
- Pharynx**, Keratoconjunctivitis sicca and buccoglossopharyngitis sicca with enlargement of parotid glands; 2 cases of Sjögren's syndrome, with pathological study of lacrimal gland and parotid glands in 1 case, 443; nasopharynx; study of 140 autopsy specimens, 546
- Phlegmon**, Pelviperineal; special type of, of broad ligament, 261
- Phosphorus**, Study of distribution of radioactive, in 3 cases of cancer, 576
- Phthalylsulfathiazole**, Surgical aspects of certain sulfonamides and antibiotic agents; collective review, 1
- Phthisis**, Some cases of intestinal tuberculosis in, with reference to prognosis, 148
- Physick-Sellheim principle** of extraperitoneal cesarean section; elucidation of technique based on 175 cases, 58
- Pilonidal sinus**, New and successful closed operative procedure for; gluteus maximus mobilization; sliding muscle graft procedure, 609
- Pituitary adrenotropic hormone**, Effect of, on cholesterol and ascorbic acid content of adrenal glands in rat and guinea pig, 102
- Pituitary extracts**, Experimental production of exophthalmos in fundulus by means of anterior, 207
- Pituitary gland**, Lesions of, accompanying obesity, 102; treatment of Cushing's syndrome, 549

- Placenta previa, Selective treatment of antepartum hemorrhage, 57
- Plasma, Protein estimations in battle casualties, 93; occurrence of fibrinolysis in shock; prothrombin time and fibrinogen of, during hemorrhagic shock, 94; relation of certain fractions of globulins of, to coagulation defect in hemophilia, 181; homologous serum jaundice following administration of commercial pooled, 183; oral feeding of, 205; amino acids in production of protein of, and nitrogen balance, 307; protein levels in normal individuals, 307; total avulsion of scalp; review of problem with case of skin graft in which thrombin fixation of, was used, 541
- Plastics, Experimental observations on use of absorbable and nonabsorbable, in bone surgery, 388
- Plastic Surgery, Fistula of penile urethra, 166; correction of superficial vascular and pigmented nevi, 395; principles in reparative, 395; anesthetic management in reconstructive surgery of mandible, 542
- Pleura, Primary endothelioma of; case in patient with chronic lymphatic leucemia, 36; acutely infected effusions of; technique of penicillin treatment, 131; penicillin treatment of empyema; 24 cases, 243; primary mesothelioma (endothelioma) of, 244; extrapleural pneumolysis in pulmonary tuberculosis, 340
- Pneumoencephalography, Midline anomalies of brain; diagnosis by, 122
- Pneumography, Subdural, 605
- Pneumolysis, Extrapleural, in pulmonary tuberculosis, 340
- Pneumectomy, Intrapericardial approach to lung root in treatment of bronchial carcinoma by dissection, 344; closure of bronchus in, and lobectomy, 454
- Poliomyelitis, Acute anterior, complicating pregnancy, 263
- Polyarthritis nodosa, Report of 11 cases with review of recent literature, 77
- Polypsis, Considerations about case with multiple gastric, hypertrophic gastritis and cancer of pyloric antrum, 330
- Pott's disease, Usefulness of low lumbar sympathectomies in surgery of obturator nerve as auxiliary method in treatment of spastic paraplegias in, 25
- Pregnancy, Congenital cataract and other anomalies following rubella in mother during; California survey, 117; synostosis of pubic symphysis; anatomic and clinical study, 167; acute anterior poliomyelitis complicating, 263; 2 hour test for, 263; rubella in, 263; puerperal infection, 265; prenatal syphilis, 266; results in 18,600 booked deliveries, 266; effects of suprarenal insufficiency on, and offspring, 311; blood disorders associated with, 370; clinicostatistical considerations based on 128 cases of extrauterine, 370; parathyroprival tetany and, 370; cesarean section for epilepsy in, 371; Hodgkin's disease and, 371, certain aspects of cancer of endometrium associated with, 476; vaginal flora during gestation, 480; haptoglobin during, confinement and postpartum period, 480; gestational neuritis, 481; congenital abnormalities in infants following infectious disease during, with special reference to rubella, third series of cases, 483; individual blood differences in relation to, with special reference to pathogenesis of pre-eclamptic toxemia, 484; adenoma of islets of Langerhans and, 567; gingivitis of; history, classification and etiology, 575; frequency of nephrostenosis during years of war, 575; significance of myoma uteri in, 576
- Pregnandioli, Ovarian and uterine grafts in woman and variations in urinary, 478
- Prematurity, Premature delivery; causes and results, 264; obstetrician's responsibility for hazards of first few days of life; anoxia and, 266
- Presentation, Bracht's maneuver in delivery of pelvic, 264
- Pressure changes, Piezoelectric crystal measurements of, in abdomen of deeply anesthetized animals during passage of high velocity missile, 568
- Proctosigmoidectomy, Abdominoperineal, for cancer of rectum; conclusions based on 5 years' experience, 467
- Prognathism, Surgical treatment of mandibular, 19
- Prolan B, Testicular choriocarcinoma accompanied by excretion of, and hypophysial changes, 492
- Prolapse, Late results of operative treatment for, of intervertebral disc in lumbar region, 336; transpyloric, of mucosa, 459; of rectum in adults, 464; uncomplicated, of ovary as cause of acute abdominal pain, 476
- Prostate gland, Clinical anatomy of tumors of, 272; topical use of clotting agents in surgery of, 483; prostatic cancer treated by orchidectomy, 489; liver changes and other effects of diethylstilbestrol during treatment of cancer of, 581
- Prostatectomy, Retropubic, 489
- Prosthesis, Retracted and short amputation stump of leg; treatment and, 589
- Prostigmine, Studies of surgical morbidity; effect of, on urinary tract in gynecological survey, 160
- Protein, Of plasma; estimations in battle casualties, 93; amino acids in production of plasma, and nitrogen balance, 307; levels of plasma, in normal individuals, 307; requirements of, in adults, 307
- Prothrombin, Occurrence of fibrinolysis in shock with observations on, time and plasma fibrinogen during hemorrhagic shock, 94; prothrombinemia in hemorrhagic diatheses and its response to vitamin K, 206; level of, of peripheral blood and sternal marrow, 392; time of, and anesthesia; clinical investigation on effects of ether and spinal anesthesia on, level of blood, 603
- Protoporphyrin, Some newer concepts of natural derivatives of hemoglobin, 393
- Pseudarthrosis, New concept of treatment of congenital, of tibia, 496
- Pseudohermaphroditism, Adrenogenital syndrome of girl with, 159
- Pseudotuberculosis, Tuberculosis of, of endometrium; clinical study and results of cytochemical explorations, 473
- Psychology, Reactions in soldiers to loss of vision of one eye, 16
- Ptois, Paralysis of ocular elevation with and without, 447
- Pubic ramus, March fractures of inferior, 283
- Puerperium, Puerperal infection, 265; haptoglobin during pregnancy, confinement and postpartum period, 480; clostridium welchii infection treated with penicillin, 483
- Pylorus, Transpyloric prolapse of mucosa, 459
- Pyuria, True infective bacterial, 168
- RADIOKYMOGRAPHY**, Cardiovascular; usefulness and future, 197
- Radiophosphorus, Histological effects of, on normal and lymphomatous mice, 89
- Radiosodium, Studies of effects of radioactive sodium and of roentgen rays on normal and leucemic mice, 89
- Radium, Cancer of oral cavity; its location and frequency, 21; primary epithelioma of trachea, 32; keloids and their treatment, 90; electroendotherapy as adjuvant to radiotherapy in uterine cancer, 97; histological study of effect of irradiation on adenocarcinoma of endometrium, 157; dosimetry measurements in roentgen irradiation of female pelvis, 199; use of, in aerolitis control program of army air forces, 201; treatment of hemangioma, 305; symposium; dosage control in interstitial therapy with, 404, treatment of carcinoma of lip, 444

- Ramsay Hunt's syndrome, Site of facial nerve lesion in cases of, 333
- Raynaud's disease, Venospasm; part in producing the clinical picture of, 76
- Recklinghausen's disease, Deformities of spine in multiple neurofibromatosis, 337
- Rectum, Cancer involving rectosigmoid and sigmoid, 255; contribution to study of anorectal cancer, 256; urinary dysfunction after excision of, 272; carcinoma of colon and, 358; colonic and proctoscopic diseases; collective review, 417; prolapse of, in adults, 464; restoration of continuity after resection of, 464; cancer of; discussion of preoperative preparation, postoperative complications, and colostomy management, 466; selection of operation and technique of abdominoperineal resection for carcinoma of, 466; abdominoperineal proctosigmoidectomy for cancer of; conclusions based on 5 years' experience, 467; colonic and proctoscopic diseases; collective review, 521; coincident removal of additional structure in resections for carcinoma of colon and, 564
- Rectus sheath, Use of, and superior pubic ligament in direct and recurrent inguinal hernia, 352
- Refrigeration, Shock and, 96; return of vision in transplanted adult salamander eyes after 7 days of, 174; in orthopedic and traumatological surgery, 499
- Rehabilitation, Of patients totally paralyzed below waist, with special reference to making them ambulatory and capable of earning own living; control of urination, 437; orthopedic and, service of Royal Air Force, 498
- Retina, Glioma of, and of brain in collateral lines in same family; genetics of glioma, 17; hercoddgenerative diseases of; attempt at classification, 544
- Rhabdomyosarcoma of skeletal muscles, 278
- Rh factor, Blood, blood derivatives and blood substitutes in obstetric and gynecologic practice, 54; survey of subtypes of white Australians, 79; report on transfusion of 2,386 liters of blood, 183; erythroblastosis fetalis in firstborn, 287; individual blood differences in relation to, with special reference to pathogenesis of pre-eclampsia toxemia, 484
- Rhizomelique, Roentgen therapy for rheumatic diseases, 508
- Rhizotomy, Spasmodic torticollis; severe organic type treated by combined operation, and fusion, 383
- Ringer's solution, Value of physiological substrates in sperm migration in selected cases of human fertility, 55
- Roentgenography, Lesions of aqueduct of Sylvius, 22; silent and masquerading intrathoracic lesions, 40; thoracic gastric cyst, 43; congenital cystic dilatation of common bile duct, 49; diagnosis of tuberculous salpingitis, 53; skeletal and pulmonary metastases from cancer of kidney, prostate and bladder, 70; osteoarthritis alkaptonuria (ochronotic) with description of case, 72; hookworm disease; small intestinal study, 88; roentgenological findings in lungs of victims of Cocoanut Grove disaster, 88; histological effects of radon-phosphorus on normal and lymphomatous mice, 89; treatment of ununited fractures of neck of femur; collective review, 105; lipoma of corpus callosum; clinicopathological study, 123; cystic disease of lung, 130; clinical and roentgenological aspects of differential diagnosis of mediastinal tumors, 137; surgery of mediastinum, 137; acute pancreatitis and splanchnic block, 153; study of ureters in bladder neck obstruction, 165; vasoseminal vesiculography and its clinical application, 168; on incidence of osteochondrosis, 177; cardiovascular radiokymography; usefulness and future, 197; examination of ankle joint in malleolar fractures, 197; roentgenology of draining bronchi from tuberculous cavities, 197; Bechterew's disease from roentgenological point of view, 198; roentgenographic appearance of temporomandibular hydrarthrosis, 207; primary mesothelioma (endothelioma) of pleura, 244; roentgenologic and gastroscopic study of gastric disease, 248; supine projection in diagnosis of lesions of corpus and posterior wall of stomach, 248; invagination of stomach, 249; surgical treatment of malignant tumors of duodenum exclusive of those arising from papilla of Vater, 252; value of, in diagnosis of tuberculosis of Bauhin's valve, 253; 4 cases of diaphragmatic intumescence, 258; nephroptosis with coexisting lesions, 269; trauma of lower urinary tract, 274; myelographic diagnosis of extramedullary cervical spinal cord tumors, 298; signs of herniation of cervical intervertebral disc, 298; correlation of gastroscopic, roentgenological, and pathologic findings in diseases of stomach; analysis of 245 proved cases, 300; localization of foreign bodies in chest, 300; review of literature pertaining to, of gastrointestinal tract for year 1944, 301; roentgenological skeletal changes in myeloma in childhood, 303; spondylolisthesis; criteria for more accurate diagnosis of true anterior slip of involved vertebral segment, 304; reflex hyperemic dissections regional to joints of extremities, 308; cephalhematoma deformans, 333; bilateral cervical ribs which became manifest after trauma of hands, 338; secondary epithelization of cavities of chronic lung abscesses, 341; roentgen and clinical problems in so-called solitary metastatic tumors in chest, 345; dysphagia due to causes other than malignant disease, 347; hiatus hernia of stomach as source of gastrointestinal bleeding, 353; congenital duodenal obstruction; 6 cases and review of literature, 353; papilloma of gall bladder, 363; sideswipe fractures, 386; angiography; evaluation of usefulness, 389; diagnosis of pancreatic cyst, 402; roentgen changes associated with pancreatic insufficiency in early life, 402; radiographic analysis of spondylolisthesis, 403; studies of spleen, 403; Ehlers-Danlos syndrome, 409; factors in diminution of mortality rate in acute intestinal obstructions, 461; subacute volvulus of terminal ileum, 462; true aneurysms of renal artery, 486; so-called retarded or occult fractures; significance of parallel projection in roentgen diagnosis of fractures, 495; diagnosis of cancer of stomach, 507; significance of minor bone injuries, 507; method of cephalography, 548; roentgenological appearance, early and late, of congenital luxation of hip treated with abduction splints, 548; subdural pneumography, 605; translumbar aortography; its diagnostic value in urology, 605; scout film of abdomen, 605; anaerobic cellulitis due to actinomyces, associated with gas production, 608
- Roentgen rays, Diagnosis of pes planus with x-rays, 72; studies of effects of radioactive sodium and oil, on normal and leucemic mice, 80; superficial burns of skin and eyes from scattered cathode rays, 200
- Roentgen therapy, Primary epithelioma of trachea, 32; primary endothelioma of pleura; report of case in patient with chronic lymphatic leucemia, 36; possibilities of, in treatment of cancer of breast, 90; histological study of effect of irradiation on adenocarcinoma of endometrium, 157; carcinoma subsequent to radiotherapeutic menopause, 158; dose measurements in roentgen irradiation of female pelvis, 199; of malignant tumors of nasopharynx, 190; newer investigations of radiation effects and their clinical applications; Pancoast lecture, 202; carcinoma of larynx following irradiation, 305; results of, of leucemia, 305; treatment of hemangioma, 305; transitional cell carcinoma, 328;

- cancer of larynx; 5 year results of concentration radiotherapy, 330; value of orchidectomy in treatment of carcinoma of male breast, 339; management of malignant tumors of testis, 379; cytological analysis of response of malignant tumors to irradiation as approach to biological basis for dosage in radiotherapy, 405; diathermocoagulation and, of malignant tumors of upper jaw, 445; for rheumatic diseases, 508; temporomaxillary actinomycosis caused by anaerobic actinomycetes of Wolff-Israel type cured by combination of sulfa drugs and, 541; supervoltage radiation; review of cases treated during an 8 year period, 1937 to 1944 inclusive, 606; for malignant teratoma of testis, 581; leucosarcoma, 611
- Rosenbach, Erysipeloid of; response to penicillin, 190
- Rubella, Congenital cataract and other anomalies following, in mother during pregnancy; California survey, 117; in pregnancy, 263; congenital abnormalities in infants following infectious diseases during pregnancy, with special reference to; third series of cases, 483
- SACRUM**, Dermoid cysts of, especially with view to treatment, 413
- Salivary glands, Adenolymphoma of parotid and submaxillary, 546
- Salpingitis, Roentgen diagnosis of tuberculous, 53
- Sarcoma, Of breast, 31; diagnosis and management of uterine carcinoma and, 52, of connective tissue spaces and of muscles of extremities, 100, bilateral primary, of kidney; report of case and review of literature, 270
- Scalenus muscles, Painful nocturnal paresthesias of upper extremities, 552
- Scalp, Arteriovenous aneurysms of, and face, 213; total avulsion of; review of problem with presentation of case of skin graft in which thrombin plasma fixation was used, 541
- Scars, Action of methylcholanthrene on certain, of skin in mice, 412; concerning the phenomena of arrest of function by neural, 449
- Scleroderma with esophageal symptoms, 37
- Sclerosing injection of polycystic kidney following surgical exposure, 373
- Sclerosis, Sympathectomy in peripheral vascular, 553
- Scotoma, Paralysis of convergence with bilateral ring, following injury to occipital region, 442
- Scrotum, Social distribution of cancer of, and of penis, 68; spontaneous gangrene of; Fournier's gangrene, 167
- Sepsis and sepsis in spinal analgesia, 194
- Septicemia, Effect of penicillin on caused by anaerobic microbes, 401
- Serum, Decrease of cholesterol ester of, in hemolytic disease of newborn, 60; determination of blood groups; use of rabbit immune, 182; jaundice following administration of commercial pooled plasma due to homologous, 183, treatment of wounds with acidophil paste and acidophil, 187; treatment of shock with, from patients with hypertension, 290
- Serum sickness, Delayed, 411
- Shell operation, Pathomechanics of hip after, 584
- Shell fragment, Late erosion of, into bladder, 488
- Shock, Investigations of postoperative; hemoconcentration, plasma protein and blood electrolytes after gastrectomy, 45; effect of intravenous administration of oxygen on, in dogs and human beings, 82; sludged blood in traumatic, precipitation and agglutination of blood flowing through vessels in crushed tissues, 93; occurrence of fibrinolysis in; prothrombin time and plasma fibrinogen during hemorrhagic shock, 94; electrolyte changes and chemotherapy in experimental burn, traumatic, and hemorrhage, 95; vascular mechanisms of terminal, 95; and refrigeration, 96; treatment of, with serum from patients with hypertension, 290; capillary and venous blood in traumatic, 403, concentrated human albumin in treatment of, 510; fatal anaphylactic, 510
- Shoulder, Rupture in aponeurosis of joint of; its treatment, 172; recurrent dislocations of, 281; experience with capsulorraphy for recurrent dislocations of, 497
- Sigmoid, Cancer of rectosigmoid and of, 255
- Sinus, Thrombophlebitis of lateral, 13; atheromatoma of, 327; problem of secondary frontal surgery of, 545
- Sjögren's syndrome, Keratoconjunctivitis sicca and buccoglossopharyngitis sicca with enlargement of parotid glands; 2 cases of, with pathological study of lacrimal gland and parotid glands in 1 case, 443
- Skeleton, Skeletal and pulmonary metastases from cancer of kidney, prostate and bladder, 70; roentgenological changes of, in myeloma in childhood, 303; rhabdomyosarcoma of skeletal muscles, 278
- Skin, Ehlers-Danlos syndrome; of 3 cases, 97; cutaneous carcinoma produced by coal tar of pilosebaceous origin, 100; superficial burns of, and eyes from scattered cathode rays, 200; epidemic keratoconjunctivitis with lesions of, 226; late recurrences in, following radical amputation of breast for carcinoma, 240; cuts graft in surgery; review of results obtained; indications and technique; report of cases, 280; repair of surface defects of upper extremity, 306; Ehlers-Danlos syndrome, 409; sacral dermoid cysts with view to treatment, 413; histamine-like action of curare and tubocurarine injected intracutaneously and intra-arterially in man, 505; amebiasis of, and subcutaneous tissue; report of 3 cases with amebic ulceration of abdominal and thoracic wall following intervention, 574; management and surgical resurfacing of serious burns, 599
- Skull, Achealasia of esophagus following depressed fracture of base of, 233; repair of cranial defects with reference to use of cancellous bone, 332; temporomaxillary actinomycosis caused by anaerobic actinomycetes of Wolff-Israel type cured by combination of sulfa drugs and roentgen therapy, 541
- Smears, Value of, from vaginal secretion in establishing differential diagnosis pertaining to ovarian activity in women, 572
- Smith-Petersen pin, Treatment of slipped upper femoral epiphysis, 283
- Spasticity, Use of curare in oil in treatment of, following injury of spinal cord, 448
- Sperm, Value of physiological substrates in migration of, in selected cases of human fertility, 55
- Sphincter of Oddi, Syndrome of, 363
- Spinal analgesia, Continuous caudal and, in cesarean section, 60; continuous, in cesarean section, 576
- Spinal anesthesia, Hypotension and; vertigo test, 296; and chloroform; comparison of mortality, 401; prothrombin time and anesthesia; clinical investigation on effects of ether and, on prothrombin level of blood, 603
- Spinal cord, Extradural spinal hemorrhage, 24; diagnosis of lumbar intervertebral disc protrusions, 123; surgery for relief of pain; anterolateral chordotomy, 237; myelographic diagnosis of extramedullary cervical tumors of, 298; lumbar herniations of intervertebral discs; value of surgical removal for naval personnel, 335; concussion of, in war wounds, 336; use of curare in oil in treatment of spasticity following injury of, 448; gestational neuritis, 487; vertebral echinococcosis, 550; vascular tumors of, associated with skin hemangiomas, 550; painful phantom limb treated by high cervical chordotomy, 551

- Spine, Extradural hemorrhage of, 24; intraspinal lipomas, 24; lumbar herniations of intervertebral discs; value of surgical removal for naval personnel, 123; mechanical results of development of tumor in craniocervical junction, 234; newer concepts in treatment of paralyzed patient due to wartime injuries of; neurosurgical complications, 236; brucellosis spondylitis, 278; roentgenographic signs of herniation of cervical intervertebral disc, 298; spondylolisthesis; criteria for more accurate diagnosis of true anterior slip of involved vertebral segment, 304; lumbar herniations of intervertebral discs; value of surgical removal for naval personnel, 335; late results of operative treatment for intervertebral disc prolapses in lumbar region, 336; deformities of, in multiple neurofibromatosis (von Recklinghausen), 337; ruptured intervertebral disc, 449.
- Splanchicotomy, Distant results in treatment of chronic pancreatitis by unilateral, 363
- Spleen, Traumatic rupture of, 49; primary congenital and secondary acquired splenic pantoematopenia, 50; special significance of accessory, 154; splenectomy, with and rationale, and comparison of reported mortality; collective review, 209; primary malignant tumors of, cysts, 257; roentgen studies of, 403; multiple peritoneal autotransplantation of tissue of, following traumatic rupture of, 471; ulcer of greater curvature of stomach penetrating into, with secondary perforation into peritoneal cavity, 561
- Splenectomy, Surgical significance of accessory spleen, 154; with reference to its historical background, indications and rationale, and comparison of reported mortality; collective review, 209
- Spint, Use of Haynes' maxillary, in case of grafting of mandible, 114; roentgenological appearance, early and late, of congenital preluxation of hip treated with abduction, 584
- Spondylolisthesis, Criteria for more accurate diagnosis of true anterior slip of involved vertebral segment, 304; radiographic analysis of, 403
- Staphylococcus, Acquired resistance of, to action of penicillin, 190, observations on penicillin, 504; local treatment of intrabulbar infections; treatment of panophthalmia by intrabulbar injections of penicillin, 544
- Sterility, Operations for, 53; therapeutic aspects of uterine insufflation in, 55
- Sterilization, Tubal, 53
- Steroids, Studies on "cold test" as method for assay of adrenocortical, 311
- Stomach, Nocturnal gastric secretion, 43; thoracic gastric cyst, 43; ulcer problem, 46; prophylaxis of peptic ulcer, 47; treatment of duodenal ulcer, 48; gastroduodenal invagination due to submucous lipoma of, 142; ulcers located high up on posterior surface of, 144; multiple carcinomas of, 145; results of medical treatment of peptic ulcer, 145; communication between duodenum and pancreas, 148; gastric retention after posterior gastroenterostomy for duodenal ulcer; prevention and treatment, 149; roentgenologic and gastroscopic study of gastric disease, 248; supine projection in diagnosis of lesions of corpus and posterior wall of, 248; invagination of, 249; case of multiple gastric polyposis, 250; diverticula of, 250; tuberculosis of, with special reference to incidence in children, 250; recurrence rate of symptoms in peptic ulcer patients on conservative medical treatment, 251; transdiaphragmatic resection of vague nerves for peptic ulcer, 251; correlation of gastroscopic, roentgenologic and pathologic findings in diseases of; analysis of 245 proved cases, 300; acute gastroduodenal obstruction (dilatation), 352; hiatal hernia of, as source of gastrointestinal bleeding, 353; 353; perforated gastric ulcer in patient with gastric neuroinoma, 353; progress after perforated peptic ulcer, 354; submucosal lipomas of; review of literature and report of case associated with carcinoma, 354; discussion of transpyloric prolapse of mucosa, 459; effect of trans-cure of vagotomy upon functions of, and early clinical course of patients with peptic ulcer, 459; 100 cases of perforated peptic ulcer; results of simple closure, 461; roentgenologic diagnosis of cancer of, 507; hypertrophic pyloric stenosis, 506; bacteriology of peptic ulcer and gastric carcinoma, 501; ulcer of greater curvature of, penetrating into spleen with secondary perforation into peritoneal cavity, 561
- Strabismus, Surgical treatment of, 561
- Streptomycin, Summary of surgical aspects of certain sulfonamides and antibiotic agents; collective review, 1; for certain systemic infections and its effect on urinary and fecal flora, 98; for tularemia, 190; resistant cocci, 191; absorption, distribution and excretion of, 308; in treatment of persistent urinary infection, 381
- Strictures, Study of tuberculous, of ureter and their complications, 271
- Sulfa drugs, Summary of surgical aspects of certain sulfonamides and antibiotic agents; collective review, 1; fistula of penile urethra, 166; typhoid-bacillus infection of surgical wound; treatment with mixture of urethane and, 191
- Sulfonamides, Summary of surgical aspects of certain, and antibiotic agents; collective review, 1; tissue changes produced in nasal mucous membrane of normal mice by prolonged local administration of some solutions containing compounds of, 18; acute hematogenous osteomyelitis in infancy, 71; masking effect of, when used in treatment of acute otitis media, 229; treatment of bacillus proteus infections with NU-455, 276; colonic and proctoscopic diseases; collective review, 417
- Supernumerary megarctet, Case of, 373
- Suppuration, Disturbances of ethmoid branches of ophthalmic nerve, with description of syndrome associated with chronic, of olfactory fissure, 448
- Suprarenal glands, Hemorrhage of, in newborn, 161; effects of suprarenal insufficiency on pregnancy and offspring, 311; assay of adrenocortical material by means of glycogen test in adrenalectomized mouse, 519
- Surgery, In malaria, 99; lumbar herniations of intervertebral discs; value of surgical removal for naval personnel, 123; treatment of deafness, 228; hydrops of labyrinth (Meniere's disease); diagnosis and results of, 229; cutis graft in; review of results obtained with comments on indications and technique; report of cases, 289; operative treatment of chronic otitis media, 376; surgical treatment of abscess of middle lobe of right lung, 341; experimental observations on use of absorbable and nonabsorbable plastics in bone, 389; injuries, 450; refrigeration in orthopedic and traumatological, 490; treatment of otosclerosis by; preliminary report on improved fenestration technique, 545; problem of secondary frontal sinus, 545; present position of, in treatment of bleeding peptic ulcer, 562; of innominate artery, 596
- Sutures, Of fingernail in crushing injuries, 83; late reactions following nerve, with integral physiological restoration of nerve, 121

- Syme amputation, Indications for, 345
 Sympathectomy, Role of, in treatment of immersion foot and frostbite, 21; for ischemia following femoral artery ligation, 25; abdominalpelvic, for relief of pain of cancer of cervix, 252; for hypertension, 337; basis for, for cancer of cervix uteri, 176; in peripheral vascular sclerosis, 551
 Sympathetic nerves, Usefulness of low lumbar sympathectomies in surgery of obturator nerve as auxiliary method in treatment of spastic paraplegia in Pott's disease, 21; interruption of sympathetic nervous system in relation to trauma, 124; surgery for hypertension, 225; effect of, and vagus nerve on activity of human uterus, 487; sympathetic block of stellate ganglion, application in orthopedic conditions, 503
 Symphysis pubis, Symptoms of, anatomic and clinical study, 161
 Syndrome, Nanthoma or lipoid granuloma of temporal bone, Hand Christian Schüller 117, of epididym of testis, 164
 Syphilis, Prenatal, 254

- TAMONADES, Colossal nasal, 19**
 Taperform, Ocular cysticercus cellulosa, report of case of parasite in vitreous, 225
 Technique, Some improvements in, of ureterocystostomy, 65; new treatment for postoperative pulmonary collapse, 81; continuous lumbar anesthesia with dilution, 103; intracardiac approach to lung root in treatment of umbilical carcinoma by dissection pneumonectomy, 314; modification of, for cure of umbilical hernia in adults, 458; selection of operation and of abdominalperitoneal resection for carcinoma of rectum, 456
 Tenions, Results of stabilizing operations on bones in paralytic feet, with or without transplantations of, 173
 Tenon's capsule, Injection of oxygen into, 15; Barker type implant for use after enucleation, 115
 Teratoma, Of anterior mediastinum in group of military age, study of 15 cases and review of theories of perovs, 455; treatment therapy for malignant, of testis, 581
 Test, Two hour pregnancy, 276; assay of adrenocortical material by means of glycogen, in adrenalectomized mouse, 519
 Testicle, Tumor of, 271; lymphosarcoma of, 379; management of malignant tumors of, 379; rate case of folliculoma of, 491; chorionepithelioma of, accompanied by excretion of prolactin and hypophyseal changes, 491
 Testosterone, Functional uterine hemorrhages and their treatment with, 250; peripheral inhibitory influence of large doses of, on epiphyseal cartilaginous growth, 370
 Tetanus, Penicillin in, 84; in African and European theaters of war from 1919-1945, 192; dust in surgical theaters as possible source of postoperative, 206
 Tetany, Parathyroid, and pregnancy, 370
 Thyroid, Structural changes in thyroid glands of patients treated with, 237; toxicity of, 232; treatment of hyperthyroidism with, with reference to toxic reactions, collective review, 413; tolerance of normal, of thyrotoxicomized, and of thyrotoxic or treated dogs to oral desiccated thyroid and to intravenous thyroxine, 415; remissions in thyrotoxicosis after, 445; "thin" drugs in thyrotoxicosis, 517
 Thyroplasty, Musculoplastic incision for posterior, 537
 Thyroctomy, Surgery of mediastinum, 137
 Thorax, Military surgery of, in forward area, 17; review of activities of thoracic center for III and IV hospital groups, 160th General Hospital, European theater of operations, from June 10, 1944 to January 1, 1945, 38; silent and masquerading intrathoracic lesions, 49; fur-

- ther experiences with endotracheal ether air for intrathoracic surgery, 87; battle wounds of cavity of, 123; pathogenesis, clinical picture and therapy of chest injuries, 138; management of war wounds of chest in base center, 139; penetrating wounds of, 219; pulmonary edema in chest wounds, 241; gas embolism in thoracic surgery, 241; penetrating wounds of chest, 245; treatment of gunshot wounds of chest in field aided by penicillin therapy, 345; studies on wounds of abdomen and, produced by 25 velocity m/c's, 291; localization of hernia lesions in, 300; mechanical factors, 343; symptoms; nonmechanical conditions of esophagus, 312; effect of transthoracic vagotomy upon functions of stomach and early clinical course of patients with peptic ulcer, 459; embolism of skin and subcutaneous tissue; report of 3 cases with arterial occlusion of wall of abdomen and of, following intervention, 314; anesthesia in surgery of, 602
 Throat, Clinical use of penicillin in infections of ear, nose and, 18; subacute edentitis of atlas following suppurative otitis of lateral sinus, 473
 Thromboembolism, Of lateral sinus, 53; physiologic considerations in case of patients with varicose veins, 300
 Thrombosis, New findings with respects to nature, prevention and treatment of, and embolism, 77; thromboembolic disease, 181; arterial, experimental and clinical conditions, 245; laws of arterial, 245; challenge of, and embolism of blood vessels, and clinical use of anticoagulants, 266; mesenteric, 319; recovery after resection with heparin, 332; thrombotic infarction of bifurcation of aorta, 521; obliteration of bifurcation of aorta (Lenke's syndrome) treated by resection of bifurcation, 525; early diagnosis and effective treatment with heparin, 528; anticoagulant therapy in management of, 528
 Thyrectomy, Prolongation of life with prevention of leukemia by, 475
 Thyroid gland, Surgery of, 140
 Thyroid gland, Chemical nature of compounds which inhibit the function of, 102; structural changes in, of patients treated with thioracil, 211; treatment of hyperthyroidism with thioracil, with particular reference to toxic reactions; collective review, 313; particular aspects of osseous growth and calcium metabolism in case of cretinism, in child of 6 years, 318; tendency to hemorrhage in thyrotoxicosis, 318; tolerance of normal, of thyroidectomized and of thioracil treated dogs to oral desiccated, and to intravenous thyroxine, 415; radioactive iodine in physiology of, 415; radioactive iodine in hyperthyroidism, 445
 Thyrotoxicosis, Tendency to hemorrhage in, 318; remissions in, after thioracil, 445; "thin" drugs in, 517
 Thyroxine, Tolerance of normal, of thyroidectomized, and thioracil or thioracil treated dogs to oral desiccated thyroid and to intravenous, 415; cretinism, ophthalmoplegia, 513
 Tilia, New concept of treatment of congenital pseudarthrosis of, 476
 Tinnitus aurium, Tympanomyotomy; surgical technique for relief of, 323
 Tissues, Changes produced in nasal mucous membrane of normal mice by prolonged local administration of some solutions containing sulfonamide compounds, 18; damage to, due to cobalt, 366
 Tongue, Tuberculous ulcer of, 230
 Tonsillectomy, Late secondary tonsillar hemorrhage, studies of aortic acid, 517
 Tools, Effects of high speed vibrating, on operators engaged in airplane industry, 607

- Torticollis, Spasmodic; severe organic type treated by combined operation, rhizotomy, and fusion, 383; subacute osteitis of atlas following suppuration of mastoid or of lateral region of, 495
- Toxemia, Syndrome of, after burns; biochemical and pathological observations and studies, 188; discussion on, of gas gangrene, 399; individual blood differences in relation to pregnancy, with special reference to pathogenesis of pre-eclamptic, 484
- Toxicity, Of thiouracil, 232; treatment of hyperthyroidism with thiouracil, with reference to toxic reactions; collective review, 313
- Toxins, Toxic manifestations associated with ertron ingestion, 97; treatment of malignant tumors by bacterial, as developed by late William B. Coley, reviewed in light of modern research, 414; therapy of experimental cancer with; influence of protozoan infections upon transplanted cancer, 517
- Trachea, Primary epithelioma of, 32
- Transfusion, Irregular hemagglutinins after, 79; transmission of infectious hepatitis by blood; 2 cases, 80; cord, in newborn infants, 161; report on, of 2,386 liters of blood, 183; erythroblastosis fetalis in firstborn, 287; therapy of infected wounds and acute infections with immuno-, 293; alterations in normal and decapsulated kidneys caused by, of heterogeneous blood, 394; accidents in, 500; blood, to recipients with "cold" agglutinins, 501
- Trauma, Rupture of spleen due to, 49; sludged blood in shock due to; microscopic observations of precipitation and agglutination of blood flowing through vessels in crushed tissues, 93; interruption of sympathetic nervous system in relation to, 124; delayed post-traumatic brain abscess, 233; of lower urinary tract, 274; bilateral cervical ribs which became manifest after, of hands, 338; probable case of appendicitis due to, 357; cystometry in study of neurogenic bladder due to, 376; osteo-articular tuberculosis and, 382; radiographic analysis of spondylolisthesis, 403; to abdomen, 472; refrigeration in orthopedic and traumatological surgery, 490; isolated luxation of fibula due to, 592
- Trench foot, Tissue damage due to cold, 596
- Tuberculosis, Some cases of intestinal, in phthisics, with reference to prognosis, 148; of stomach with special reference to incidence in children, 250; value of roentgenology in diagnosis of, in Bauhin's valve, 253; extrapleural pneumolysis in pulmonary, 340; osteoarticular, and trauma, 382; evolution of tuberculous osteitis of femoral neck, 383; of cervix, 473; pseudo, of endometrium; clinical study and results of cytochemical explorations, 473; surgical treatment of intestinal, 503; of renal pyramids, 578
- Tularemia, Streptomycin for, 590; oculoglandular, 544
- Tumors, Delimitation of subcuticular, by direct electrography, 23; prognosis of benign lesions of female breast, 28; silent and masquerading intrathoracic lesions, 40; morphological study on chorioepithelial proliferations, based on 10 cases, 61; growth of mammalian, in fertile eggs; is filtrable cancer virus produced, 99; of sublingual glands, 118; clinical and roentgenological aspects of differential diagnosis of mediastinal, 137; surgery of thymus gland, 140; neoplasms in apparently normal ovaries, 158; adrenogenital syndrome of girl with pseudohermaphroditism, 159; of renal pelvis, 164; roentgen treatment of malignant, of nasopharynx, 199; nontraumatic hematomas, 233; mechanical results of development of, in craniovertebral cavity, 234; metastatic, of brain, 234; skeletogenous, of mammary gland, 239; primary, of lung, 242; pseudomyxoma of peritoneum, 248; surgical treatment of malignant, of duodenum exclusive of those arising from papilla of Vater, 252; primary malignant, of spleen, with reference to endotheliomas, 257; contribution to case knowledge and histology of Brenner, 259; hemangioma of kidney, 270; clinical anatomy of prostatic, 272; of testicle, 273; myelographic diagnosis of extramedullary cervical, of spinal cord, 298; roentgenological skeletal changes in myeloma in childhood, 303; treatment of hemangioma, 305; neutralization of inhibition of growth of, 308; cephalohematoma deformans, 333; roentgen and clinical problems in so-called solitary metastatic, in chest, 345; mediastinal, 349; rupture of, of kidney and hydronephroses, 375; management of malignant, of testis, 379; dosage control in interstitial radium therapy, 404; cystological analysis of response of malignant, to irradiation as approach to biological basis for dosage in radiotherapy, 405; treatment of malignant, by bacterial toxins as developed by late William B. Coley, reviewed in light of modern research, 414; cataract associated with intraocular, 443; rare instance of fibromyoma of ear lobes, 444; diathermo-coagulation and roentgen therapy of malignant, of upper jaw, 445; malignancy of, of hypophysis; critique and case report, 447; complete extracapsular excision of, of hypophysis, 447; adenocarcinoma of urachus involving urinary bladder, 474; clinical observations on fibromyomas of uterus, 474; investigation of ovarian, 477; contribution to pathology and clinical course of granulosa cell, 477; sedimentation rate in hypernephroma, 485; early metastases of hypernephroma in third metacarpal bone of pulsating character, 485; displacement of kidney consequent upon spontaneous perineal hematoma, 485; of renal pelvis, 487; pulsating benign giant cell, of bone; report of case and review of literature, 494; cancer in childhood, 515; cranio-pharyngealomas in children, 549; suprasellar meningiomas associated with scotomatous field defects, 549; vascular, of spinal cord associated with skin hemangiomas, 550; prognosis and problems in renal, 578; solid, of epididymis, 581; exarticulation of lower extremities for malignant, 588; supervoltage radiation; review of cases treated during 8 year period 1937 to 1944 inclusive, 606
- Tunica vasculosa lentis, Persistence and hyperplasia of primary vitreous; retrolental fibroplasia or, 16
- Tympanosympathectomy, Surgical treatment for relief of tinnitus aurium, 325
- Typhoid-bacillus infection of surgical wound; treatment with urethane-sulfanilamide mixture, 191
- Tyrosinemia, Summary of surgical aspects of certain sulfonamides and antibiotic agents; collective review, 1
- ULCER, Esophageal peptic, 37; nocturnal gastric secretion, 43; problem of, 46; prophylaxis of peptic, 47; treatment of duodenal, 48; lesions of vulva, 54; penicillin and vitamin C in treatment of hypopyon, 116; located high up on posterior surface of stomach, 144; results of medical treatment of peptic, 145; gastric retention after posterior gastroenterostomy for duodenal; prevention and treatment, 149; tuberculous, of tongue, 230; Curling's, in experimental burns; effect of penicillin therapy: correlation of observations with other recent evidence regarding pathogenesis of peptic, 250; recurrence rate of symptoms in patients with peptic, on conservative medical treatment, 251; transdiaphragmatic resection of vagus nerves for peptic, 251; retrobulbar, of duodenum, 252; tuberculous ulcerative colitis or ulcerative colitis with superimposed tuberculous, 253; treatment of perforated gastric and duodenal, 353; perforated gastric, in patient with gastric neuroinoma,

- June 10, 1944 to January 1, 1945, 38; injuries of urinary tract, 68; wounds of urogenital tract, 69; repair of soft tissue wounds, 82; contribution of anatomy to, 93; plasma protein estimations in battle casualties, 93; neurosurgical service in evacuation hospital, 125; battle wounds of thoracic cavity, 128; management of wounds of chest in base center, 139; mechanical intestinal obstruction following wounds of abdomen, 147; last "hate," 155; delayed internal fixation of compound battle fractures in Mediterranean theater of operations, 176; tetanus in African and European theaters of, from 1939 to 1945, 192; anesthetic procedures used in general hospital in communication zone with analysis of 2,000 anesthetics, 193; use of radium in aeritis control program of army air forces, 201; treatment of jaw and face casualties in British army, 225; newer concepts in treatment of paralyzed patient due to wartime injuries of spine; neurosurgical complications, 236; penetrating wounds of chest, 240, 245; studies on wounds of abdomen and thorax produced by high velocity missiles, 291; wartime laryngeal injuries, 329; spinal cord concussion in wounds of, 336; wounds of liver, 362; nongonococcal urethritis in Australian troops stationed in Borneo, 377; battle injuries of arteries in World War II, 390; principles in reparative plastic surgery, 393; lid repair and reconstruction, 442; orthopedic and rehabilitation service of Royal Air Force, 498; problem of nutrition in postoperative care of abdominal wounds of, 502; investigation of role of chemotherapy in wound management in Mediterranean theater, 502; colonic and proctoscopic diseases; collective review, 521; frequency of nephrostenosis during years of, 575; wound healing with low vitamin C level, 600; causes of amputations in battle casualties with emphasis on vascular injuries, 600
- Waterhouse-Friedrichsen syndrome, Report of case of acute hemorrhagic adrenalitis, 63
- Wilms' tumor, Study of, 368
- Work, Physical capacity for; principles of industrial physiology related to evaluation of capacity of physically impaired for, 205
- Wounds, Summary of surgical aspects of certain sulfonamides and antibiotic agents; collective review, 1; war, of urogenital tract, 69; early results of treatment of gunshot, of limb joints aided by penicillin therapy, 74; repair of soft tissue, of war, 82; bacteriology of septic fingers, 83; penetrating head, 121; battle, of thoracic cavity, 128; management of war, of chest in base center, 139; mechanical intestinal obstruction following war, of abdomen, 147; early results in short series of cases of gunshot, of abdomen, 156; vascular injuries of extremities in battle casualties, 179; early management of facial injuries, 185; treatment of, with acidophil paste and acidophil serum, 187; synthetic production of vitamin K and its use in hemorrhages and treatment of, 187; typhoid-bacillus infection of surgical; treatment with urethane-sulfanilamide mixture, 191; synthetic adhesives in treatment of, of liver and other surgical conditions; preliminary report, 195; penetrating, of chest, 240, 245; treatment of gunshot, of chest in field aided by penicillin therapy, 245; gunshot, of abdomen, 257; studies on, of abdomen and thorax produced by high velocity missiles, 291; clostridia infections in, of war on Karelian isthmus, 293; therapy of infected, and acute infections with immunotransfusions, 293; experimental study on healing of, with special reference to action of heart extract powder (Doljanski), 311; spinal cord concussion in war, 336; intestinal obstruction following abdominal battle, 355; war, of liver, 362; battle injuries of arteries in World War II, 390; air hygiene in dressing rooms for huns or major, 397; cerebral fungus following penetrating, 447; problem of nutrition in postoperative care of abdominal, of warfare, 502; investigation of role of chemotherapy in management of, in Mediterranean theater, 502; colonic and proctoscopic diseases; collective review, 521; brachial plexus paralysis from gunshot, 551; of urinary bladder, 570; healing of, with low vitamin C level, 600; anaerobic infection and gas gangrene of, of war in casualties from Philippine Islands, 601
- Wrist, Fractures of carpal scaphoid, 281; early metastases of hypernephroma in third metacarpal bone of pulsating character, 485
- XANTHOMA or lipoid granuloma of temporal bone—Hand-Christian-Schuller syndrome, 117

AUTHOR INDEX—ABSTRACTS—VOLUME 83
